The C<sub>24</sub>–C<sub>40</sub> fragment of (–)-pulvomycin was prepared in enantiomerically pure form using a concise synthesis method (15 linear steps from D-fucose, 6.8% overall yield) featuring a diastereoselective addition to an aldehyde, a β-selective glycosylation and a Stille cross-coupling as the key steps.

The antibiotic pulvomycin was first isolated in 1957 from a *Streptomyces* species but due to the limited analytical data no structure was assigned to the compound.<sup>1</sup> In 1963, Akita *et al.* isolated a natural product from *Streptomyces albosporus* var. *labilomyceticus*,<sup>2</sup> which they called labilomycin and which was later shown to be identical to pulvomycin.<sup>3</sup> Extensive analytical work by Smith *et al.* revealed the constitution of the natural product (Fig. 1) as well as the absolute and relative configuration at most stereogenic centers except for C<sub>32</sub> and C<sub>33</sub>.<sup>4</sup> The assignment was confirmed and the complete configuration was eventually proven by a crystal structure (1.4 Å resolution) of pulvomycin with the bacterial elongation factor Tu (EF-Tu).<sup>5</sup> It is well established that pulvomycin is a potent inhibitor of EF-Tu and it therefore represents a promising lead compound for the development of new antibiotics.<sup>6</sup>

While synthetic reports on pulvomycin are scarce, the biosynthesis of the pulvomycin aglycone has been elucidated by labeling experiments.<sup>7</sup> Our own interest in pulvomycin was triggered by our previous studies on the synthesis<sup>8</sup> and antibiotic activity<sup>9</sup> of thiazole peptides, such as the GE factors and the amythiamicins. It has been shown that the EF-Tu binding site of pulvomycin is in close proximity to the binding site of thiazole peptides.<sup>10</sup> The synthesis of pulvomycin and pulvomycin analogues might consequently help to further investigate the many facets of EF-Tu activity.<sup>11</sup> Apart from its biological activity, pulvomycin presents itself as a formidable synthetic challenge due to its complex and labile structure. In this communication

Fig. 1 Structure and compound numbering of (–)-pulvomycin.

Scheme 1 Retrosynthetic disconnection of the title compound **1** leading to D-fucose (**2**) as an appropriate carbohydrate substrate.

we disclose the enantioselective synthesis of a suitably protected C<sub>24</sub>–C<sub>40</sub> fragment **1** (Scheme 1) of pulvomycin.

Retrosynthetically, it was envisioned that ketone **1** (TBDPS = *tert*-butyldiphenylsilyl) could be derived from commercially available D-fucose (**2**), which shows the correct configuration at the stereogenic centers (C<sub>36</sub>–C<sub>39</sub>) of the pyranose ring. In order to establish the desired β-configuration at the glycosidic center an appropriate neighbouring group, *e.g.* an acetate, was required (at carbon atom C<sub>36</sub>)<sup>12</sup> and the methyl ether linkage was to be introduced after glycosylation. There was precedence for the differentiation of the two equatorial hydroxy groups at C<sub>36</sub> and C<sub>37</sub> of D-fucose.<sup>13</sup>

Regarding the C<sub>24</sub>–C<sub>34</sub> fragment, it seemed best to assemble the triene<sup>14</sup> after the glycosylation step by an appropriate cross-coupling reaction, *e.g.* between C<sub>29</sub> and C<sub>30</sub>. The stereogenic center at C<sub>33</sub> appeared to be accessible from the chiral pool, *e.g.* from lactic acid, while the adjacent stereogenic center was to be introduced by a diastereoselective reaction.

The acetylation of D-fucose (**2**) (Scheme 2) proceeded quantitatively delivering the tetraacetate as an α/β-mixture (α/β = 95/5)

of anomers.<sup>13</sup> Conversion to the required thioacetal **3** proceeded best in our hands with ethanethiol and BF<sub>3</sub>·OEt<sub>2</sub> in CH<sub>2</sub>Cl<sub>2</sub>,<sup>15</sup> which delivered depending on the reaction conditions and on the reaction scale variable amounts of separable α/β-isomers (see the ESI† for further details).

Since the relative configuration at the anomeric center was irrelevant for the desired glycosylation reaction, the α/β-mixture of **3** was taken into the four-step procedure previously described for the selective preparation of alcohol β-**4**<sup>13</sup> and it furnished the desired product **4** as an α/β-mixture (α/β ≈ 50/50) in a total yield of 60% over six steps from D-fucose (**2**). Conversion of the equatorial alcohol **4** to silyl ether **5** required elevated temperature (60 °C) and a prolonged reaction time (3 d).

As mentioned above, it was planned to introduce the stereogenic center at C<sub>32</sub> by a diastereoselective reaction induced by the adjacent stereogenic center at the carbon atom C<sub>33</sub>. Surprisingly, the reduction of a (*S*)-lactate-derived, *para*-methoxybenzyl (PMB) protected alkynyl ketone<sup>16</sup> produced the desired alcohol **7** either in low yields or with insufficient diastereoselectivity (see the ESI† for further details). As an alternative approach, (*S*)-lactate-derived aldehyde **6**<sup>17</sup> was alkynylated with TMS-acetylene under chelation control<sup>18</sup> yielding alcohol **7** and its epimer *epi*-**7** in 81% yield and in a diastereomeric ratio (d.r.) of 87/13 (Scheme 3). The diastereomerically pure product **7** was isolated in 65% yield.

Protection of the secondary alcohol proceeded smoothly at ambient temperature and the PMB group was cleaved oxidatively with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ)<sup>19</sup> to deliver alcohol **8**. The enantiomeric excess (ee) of alcohol **8** was established by chiral HPLC analysis and comparison with a racemic sample (see the ESI† for further details). Gratifyingly, the glycosylation reaction, when performed with *N*-iodosuccinimide (NIS) and trifluoromethanesulfonic acid (HOTf) as activating agents,<sup>20</sup> delivered a single diastereomerically pure product **9**, which was shown to have the desired β-configuration.<sup>21</sup> Reductive removal of the acetyl groups with diisobutylaluminium hydride (DIBAL-H)<sup>22</sup> produced 1,3-diol **10**, which was converted into the respective dimethylether **11** upon treatment with an excess (10 equiv.) of Meerwein salt and proton sponge [1,8-bis(dimethylamino)naphthalene].<sup>23</sup> Less electrophilic methylating reagents (MeOTf, MeI) in combination with appropriate bases failed to react or led to substrate decomposition. Selective desilylation of the alkyne was achieved with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU).<sup>24</sup>

With alkyne **12** in hand, various approaches to potential cross-coupling substrates were pursued. It was found that the

Scheme 3 Assembly of the C<sub>28</sub>-C<sub>40</sub> fragment via glycosylation of enantiomerically pure (≥98% ee) alcohol **8** with glycosyl donor **5**.

Pd-catalyzed hydrostannylation with Bu<sub>3</sub>SnH<sup>25</sup> can be successfully performed with alkyne **12** delivering stannane **13** in 44% yield (Scheme 4). Iodide **14** was obtained from stannane **13** upon treatment with iodine in dichloromethane (85% yield).<sup>26</sup> The alkyne hept-3-en-1-yne-5-ol<sup>27</sup> seemed to be the most suitable precursor for iodide **15** and stannane **16**. The compound was available from bis-1,4-(trimethylsilyl)buta-1,3-diyne in four steps and an overall yield of 53% (see the ESI† for further details). Stannylation of hept-3-en-1-yne-5-ol with Bu<sub>3</sub>SnH was readily achieved employing the Cu-based protocol of Betzer *et al.*<sup>28</sup> to deliver stannane **16** in 79% yield. As for **14**, iodide **15** was generated by iodo-de-stannylation employing iodine in dichloromethane (79% yield).

While attempted Stille cross-coupling reactions<sup>29</sup> of stannane **13** and iodide **15** failed, the desired C-C bond formation proceeded smoothly, when performed with the carbohydrate building block as the electrophile. Iodide **14** and stannane **16** underwent a clean cross-coupling employing Pd(MeCN)<sub>2</sub>Cl<sub>2</sub>

Scheme 4 Stille cross-coupling of building blocks **13** and **15** as key step for the assembly of the title compound.

(10 mol%) as the catalyst.<sup>30</sup> Alcohol **17** was obtained in 87% yield and was immediately further oxidized to the desired ketone by treatment with an excess (30 equiv.) of MnO<sub>2</sub>. Despite a pronounced long wavelength absorption ( $\lambda_{\text{max}} = 308 \text{ nm}$ ,  $\epsilon = 28\,035 \text{ M}^{-1} \text{ cm}^{-1}$  in MeCN), trienone **1** appears to be more stable than alcohol **17** ( $\lambda_{\text{max}} = 271 \text{ nm}$ ,  $\epsilon = 39\,350 \text{ M}^{-1} \text{ cm}^{-1}$  in MeCN; shoulder at  $\lambda_{\text{max}} = 282 \text{ nm}$ ,  $\epsilon = 31\,180 \text{ M}^{-1} \text{ cm}^{-1}$ ) and could be stored for one week at  $-25 \text{ }^\circ\text{C}$  in the dark.

In summary, the enantiomerically pure western fragment **1** of (–)-pulsomycin was synthesized in 15 linear steps. The fragment comprises the carbohydrate part (labilose, C<sub>35</sub>–C<sub>40</sub>) of the natural product and one of its three triene components (C<sub>24</sub>–C<sub>34</sub>). Should an aldol-type reaction of fragment **1** with a suitable Eastern fragment not be successful, stannane **13** and iodide **14** offer suitable options to connect the protected glycoside fragment to the rest of the molecule.

This project was supported by the *Deutsche Forschungsgemeinschaft* (Ba 1372-18/1), by the *TUM Graduate School*, and by the *Fonds der Chemischen Industrie*. Olaf Ackermann and Florian Mayr are acknowledged for help with the HPLC analyses.
