Lehrstuhl II für Technische Chemie

Dry reforming- From understanding the elementary steps to better catalysts

Yu Lou

Vollständiger Abdruck der von der Fakultät für Chemie der Technischen Universität
München zur Erlangung des akademischen Grades eines

Doktors der Naturwissenschaften (Dr. rer. nat.)

genehmigten Dissertation.

Vorsitzender: Univ.-Prof. Dr. Kai-Olaf Hinrichsen

Prüfer der Dissertation:

1. Univ.-Prof. Dr. Johannes A. Lercher
2. Univ.-Prof. Dr. Tom Nilges

Die Dissertation wurde am 15.02.2017 bei der Technischen Universität München
eingereicht und durch die Fakultät für Chemie am 16.03.2017 angenommen.

Statutory Declaration

I declare that I have authored this thesis independently and that I have solely used the declared (re)sources and that I have marked all material, which has been quoted either literally or by content from the used sources. At the end of each chapter all collaborators are named and their specific contribution is addressed. Published content of this thesis is clearly marked.

_____ , _____

One needs 3 things to be truly happy living in the world: something to do, someone to love, something to hope for.

Acknowledgements

Completion of this doctoral dissertation was possible with the support of several people.

First, I am very grateful to Professor Johannes A. Lercher, the supervisor of my doctoral work. Thank you for offering me the position in this international group and giving me the opportunity to work on this interesting project. It has been a real pleasure to do this thesis under your supervision and I would thank you for your insightful guidance and support throughout this project.

I am also grateful to Professor Andreas Jentys. The discussions with you throughout my doctoral work are really memorable. Thank you for giving me the freedom to pursue my own ideas that I have been interested in and for your valuable scientific advice.

I am also very thankful to Dr. Yue Liu for his insightful thoughts during the numerous times of discussion in the final stage of my graduation study.

Next, I would like to thank the members of CO₂ group. I thank Edith Berger for the organization of TGA measurements and schlenk system. And special thanks to my co-worker Matthias Steib, who has contributed to the EXAFS measurements and shared his knowledge with me.

I would like to thank all the technical and administrative staffs for their kind assistance. I thank Xaver Hecht for the BET and hydrogen chemisorption measurements and for solving technical problems. Martin Neukamm is acknowledged for his support in the order of chemicals and labware and AAS measurements. I also thank Andreas Marx for his efforts with all the electronic devices. Stefanie Seibold, Helen Brenner, Bettina Federmann, Karen Schulz and Ulrike Sanwald are acknowledged for their administrative assistance.

My colleagues, Dr. Elisabeth Hanrieder and Dr. Sebastian Grundner, who spared their time to perform TEM measurements for my samples, I acknowledge your contributions. My officemates, Yuanshuai Liu, Ruixue Zhao, Andreas Ehrmaier, Sebastian Eckestein, Dr. Yulia Martynova, Dr. Christian Gärtner, Dr. Linus Schulz and Dr. Wenhao Luo are acknowledged for a friendly and cooperative work environment. I am very grateful to all the members of this international group for sharing their time with me. Prof. Dr. Xuebing Li, Dr. Hui Shi, Dr. Yongzhong Zhu, Prof. Dr. Chen Zhao, Dr. Oliver Y. Gutiérrez, Dr. Maricruz Sanchez, Dr. Eszter Baráth, Dr. Erika E. Ember, Dr. Yanzhe Yu, Dr. Xianyong Sun, Dr. Jiayue He, Dr. Baoxiang Peng, Dr. Robin Kolvenbach, Dr. Yuchun Zhi, Dr. Vishnuvarthan Muthusamy, Dr. Eva Schachtl, Dr. Tobias Berto, Sebastian Foraita, Dr. Stanislav Kasakov, Dr. John Ahn, Dr. Bo Peng, Dr. Wenji Song, Dr. Sebastian Müller, Dr. Maximilian Hahn, Dr. Jennifer Hein, Dr. Jeongnam Kim, Dr. Luis Francisco Gonzalez Peña, Manuel Wagenhofer, Martina Braun, Guoju Yang, Yang Song, Yang Zhang, Peter Hintermeier, Sylvia Albersberger, Daniel Melzer, Wanqiu Luo, Takaaki Ikuno and Ferdinand Vogelgsang, Claudia B. Himmelsbach, Moritz Schreiber, Marco Peroni, Kai Sanwald, Martin Baumgärtl, Xi Chen, Guanhua Cheng, Christoph Denk, Takaaki Ikuno, Felix M. Kirchberger as well as other members whose names are not mentioned here, for their friendship and all the great times that we have shared.

Furthermore, I would like to express my gratitude to our research partners from TU Wien (TUW) and Institute of isotopes (Iol). Prof. Dr. G. Rupprechter, Asst. Prof. Dr. K. Föttinger, Dipl. A. Wolfbeisser and Dr. A. Horvath are acknowledged for their scientific advice and insightful discussions.

Last but not least, I owe a great debt of thanks to my family for their love, encouragement and understanding years by years. My parents have offered me unconditional support during my master degree and further PhD study in Germany. To my lovely wife Yanping, who inspired me, provided constant encouragement during the entire process and gave me the most precious gift that I've ever received during my life, my lovely daughter Lucy.

Thanks to all of you

Yu Lou

Abstract

The activity of Ni/ZrO₂ catalysts for dry reforming and its thermal stability are significantly enhanced by activation and regeneration in presence of CO₂. The exposure to CO₂ mitigates the decoration of ZrO₂ on nickel surface and creates a large ZrO₂-Ni interface. Small and well-defined Ni particles supported on SiO₂ and ZrO₂ were prepared by a novel approach via self-assembled nano-capsules. Ni/ZrO₂ with small metal nanoparticles contains a high fraction of perimeter Ni, which is better accessible to surface O species facilitating carbon removal and which leads to enhanced DRM stability.

Kurzzusammenfassung

Die Aktivität von Ni/ZrO₂ für das Trockenreformieren und seine thermische Stabilität wird durch Aktivierung und Regenerierung in Gegenwart von CO₂ deutlich erhöht. Die CO₂ Behandlung vergrößert die Grenzfläche zwischen Ni und ZrO₂. Kleine, einheitliche Ni-Partikel wurden durch einen neuen Ansatz der selbstorganisierenden Nanokapseln geträgert. Dieser Katalysator besitzt kleine, stabile Ni-Partikel geträgert auf ZrO₂. Dies erleichtert die Entfernung des Kohlenstoffs von der Ni-Oberfläche und führt so zu einer stabilen katalytischen Aktivität für das Reformieren von Methan mit CO₂.

Chapter 1

Introduction

1.1. General background

During the course of global economic sustainable development, human beings are confronted with immense pressures in population, resources and the environment. The energy problem has received much attention in recent years. In view of depletion in stock of petroleum reserves, a more widespread use of natural and renewable energy sources have been recognized as an important contribution to a sustainable development.

Methane is the most abundant hydrocarbon on our planet, which exists in enormous quantity in natural gas and biogas and also in the form of gas hydrate at the continental slopes and in permafrost areas.¹ The total reserves of natural gas was proved in 2015, with a total storage capacity of $186.9 \times 10^{12} \text{ m}^3$,² which is sufficient to meet 52.8 years of current production. Estimates of the amount of methane increased from $125.7 \times 10^{12} \text{ m}^3$ in the last 25 years (shown in Figure 1-1), as a consequence of the improved production technology allowing access to unconventional sources, i.e. shale gas fracking.³

Figure 1-1. Total reserves of natural gas in the last 25 years. The amount of natural gas in crystalline hydrates is excluded from this estimates.

Additionally, the reserves-to-production (R/P) ratio decreased sharply in the past 10 years, as the increased natural gas production from $2.79 \times 10^{12} \text{ m}^3$ to $3.54 \times 10^{12} \text{ m}^3$ (shown in Figure 1-2). It is worth noting that enormous amount of natural gas in crystalline hydrates is excluded from this estimate, which varies from $1000 \times 10^{12} \text{ m}^3$ to $5000 \times 10^{12} \text{ m}^3$.⁴ Consequently, the utilization of methane is getting more economically attractive in terms of its enormous reserves.

Figure 1-2. Natural gas production in the last 10 years.

However, instead of use as chemical feedstock, the majority of methane is consumed for heating and electrical generation.⁵ It is reported that less than 10 % of natural gas was used as input for producing chemicals.¹ Thus, a more efficient use of the natural gas, especially methane, is becoming more attractive.

1.2. Syngas production and reforming technology

Syngas is a mixture of carbon monoxide and hydrogen, which can be produced from a variety of sources, including natural gas, coal, biomass, or virtually any hydrocarbon feedstock via steam reforming, partial oxidation and gasification.⁶ Syngas is used as a versatile intermediate resource for production of hydrogen, ammonia, methanol, and synthetic hydrocarbon fuels.

Figure 1-3. Schematic representation of natural gas production from a variety of sources and of its transformation to chemicals and fuels.⁶

Until now, hydrocarbon reforming, particularly steam reforming of methane (SRM) (Equation 1-1), is generally the largest and widely used method in industry to produce hydrogen and carbon monoxide. The steam reforming reaction is an endothermic process, which requires energy input to meet the endothermicity of the reaction.^{7,8} During this process, CO₂ is produced along with syngas. However, the removal and disposal of CO₂ is a major issue in the petrochemical industrial.⁹

(Equation 1-1)

The partial oxidation of methane (POM) is a mildly exothermic process, which however, can result in hot-spot formation at high space velocity, leading to higher risks and greater difficulties for process control.

(Equation 1-2)

Hence, during the last several years, in addition to steam reforming and partial oxidation, there has been renewed interest in the dry reforming of methane (DRM) for the production of synthesis gas. Compared to SRM and POM, DRM has many advantages. It produces syngas with a H_2/CO ratio close to 1, which is a preferable feed for Fischer-Tropsch synthesis.¹⁰ Syngas with high H_2/CO ratio, i.e. those from SRM with a H_2/CO ratio of 3 and from POM with a H_2/CO ratio of 2, favors methanation and suppress chain growth in Fischer-Tropsch synthesis.^{11,12} Furthermore, the separation of CO_2 from natural gas are not required since many remote natural gas fields contain significant amounts of CO_2 . Additionally, dry reforming also provide a pathway to reduce the CO_2 and CH_4 , which are regarded as important greenhouse gases.

Figure 1-4. Schematic representation of dry reforming to form syngas and its transformation into fuels via Fischer-Tropsch synthesis

The main problem for the DRM reaction is the rapid deactivation of supported metal catalysts caused by sintering of metal particles and coke formation. In order to reach acceptable conversion levels, high temperatures above 900 K are required.¹³ Therefore, a significant challenge to stabilize dry reforming catalyst is reducing the sintering of the active metal.¹⁴ Furthermore, deactivation of the catalysts by coke formation is also serious during DRM reaction. Coke formation on catalysts and walls of the reactor pipes are serious problems in many industrial reactors. In severe cases, it leads to blockage of reactor tubes. Thus, many efforts have recently been made in this area in developing suitable DRM catalysts, which is stable against sintering and coke formation.

1.3. Dry reforming

1.3.1. Reaction networks

In dry reforming reaction, CH₄ reacts with CO₂ to form CO and H₂ (Equation 1-3). This reaction is highly endothermic, thus, high temperature is required in order to reach an acceptable conversion. The minimum operating temperature for DRM reaction at atmospheric pressure was thermodynamically determined,¹⁵ which showed that the DRM become thermodynamically favorable at the temperature above 913 K with a feed ratio of CH₄ : CO₂ = 1:1.

(Equation 1-3)

The reverse water gas reaction (RWGS) (Equation 1-4), which occurs during DRM reaction, is slightly endothermic. In this reaction, the consumption of H₂ leads to a H₂/CO ratio less than unity, and the generated H₂O can further react with CH₄ in the steam reforming (Equation 1-1). At the temperature higher than 1093 K, the RWGS will not take place.

(Equation 1-4)

DRM reaction suffers from coke deposition on the catalysts, which is formed predominantly via the Boudouard reaction (Equation 1-5) and methane decomposition (Equation 1-6).¹⁶⁻¹⁸ The Boudouard reaction is an exothermic process, which shows a greater preference towards carbon deposition at low temperature. It was reported that at the temperature above 973 K,¹⁵ this reaction lies completely on the side of carbon monoxide and, thus, no carbon is formed via CO disproportionation reaction.

(Equation 1-5)

Methane decomposition reaction (Equation 1-6) is also an endothermic reaction and thermodynamically favored at high temperatures. The lower limiting temperature of 830 K¹⁵ was determined at atmospheric pressure.

(Equation 1-6)

Besides, the reverse carbon gasification reaction (Equation 1-7) also forms carbon, which is considered to have less influence on the carbon formation than methane decomposition and Boudouard reaction.

(Equation 1-7)

Thus, as aforementioned reaction networks, DRM is thermodynamically preferable at the temperature above 1000 K¹⁹, at which the carbon formation via CO disproportionation reaction is kinetically inhibited and the DRM reaction is simultaneously facilitated.

1.3.2. Effect of temperature

The reaction equilibrium constants of aforementioned reactions as a function of temperature was summarized in Figure 1-5.²⁰ Lower reaction temperature, i.e. below 873 K, has a significantly greater preference for carbon formation via Boudouard reaction (Equation 1-5) and reverse carbon gasification reaction (Equation 1-7). At the temperature above 1023 K, the equilibrium constant of the DRM reaction (Eq. 1-3) increased dramatically than that of the side reactions

(Equation 1-4 and 1-6). Therefore, in order to minimize the impact of coke formation during DRM reaction, high reaction temperatures are more favorable.

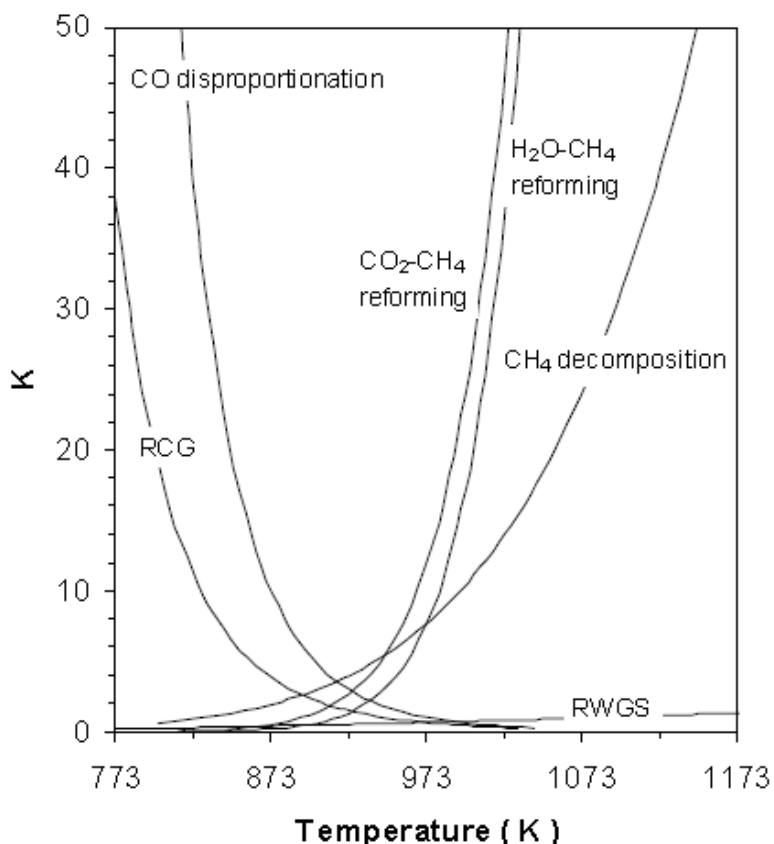

Figure 1-5. Equilibrium constants of reactions involved in networks of DRM as a function of temperature.²⁰

Furthermore, the variation of equilibrium composition as a function of reaction temperature is shown in Figure 1-6.²¹ The equilibrium composition is calculated at total pressure of 1 atm and initial CH₄/CO₂ ratio of 1/1. As shown in Figure 1-6, the composition of H₂ and CO increases while the fractions of H₂O, CH₄ and CO₂ decreases. The molar ratio of H₂ to CO becomes closer to unity at higher temperatures. Thus, DRM is preferable at a higher temperature to achieve high conversion of CH₄ and CO₂ and to minimize the impact of RWGS on the H₂/CO ratio.

Figure 1-6. Variation of equilibrium composition with temperatures.

1.3.3. Effect of pressure

In the DRM reaction, the number of gaseous molecules increases and the pressure also increases. The influence of the pressure on the equilibrium compositions was illustrated in Figure 1-7, which showed that lower pressure favor the complete conversion of CH₄ and CO₂ to form CO and H₂. Nonetheless, in view of the industrial process, high pressure allow to minimize the reactor size and energy use.²²

Figure 1-7. Variation of equilibrium compositions with increasing reaction pressure at 1073 K.

1.4. Mechanism of dry reforming of methane

Carbon dioxide reforming of methane has been studied over the years by a large number of research groups and many contributions have been made in this area, both on the theoretical side²³⁻²⁹ and on the applications to the industrial process³⁰⁻³². Nevertheless, little research has been focus on the reaction kinetics and its mechanism. Until now, no generally accepted kinetic model has been published yet.

Nonetheless, it is widely accepted that the dissociative chemisorption of CH₄ denote the initial step of the reforming reaction, which occurs on the active metal surface³³⁻³⁷. The stepwise decomposition of CH₄ and formed H and CH_x species have been confirmed by Osaki et al.³⁸:

(Equation 1-8)

(Equation 1-9)

(Equation 1-10)

(Equation 1-11)

where M stands for the surface metal active sites. The CH_x intermediates formed during dry reforming of methane were determined in situ via pulse surface reaction rate analysis (PSRA).³⁹ The value of x varied from 0 to 3 on supported Ni catalysts^{10,40,41} and 0.75 on supported Co catalyst⁴². In the 1970s Matsumoto and his coworkers have proved that different CH_x species was formed on Ni catalysts after adsorption of hydrocarbons and CH_x intermediates with lower values of x were more likely to form carbonaceous deposits.⁴³⁻⁴⁵ Furthermore, the cleavage of the first C-H bond was concluded to be the rate determining step for all reforming and decomposition reactions of methane on noble metals as well as on metallic Ni.³³⁻³⁷

Nevertheless, there are mainly two different reaction pathways proposed for CO_2 activation on dry reforming catalysts. Wei and Iglesia proposed in their research that methane and CO_2 are activated on the metal surface through a Langmuir-Hinshelwood mechanism.³³⁻³⁷ The main steps involved are illustrated in Figure 1-8.²⁸

Figure 1-8. Schematic representation of dry reforming via a mono-functional mechanism. The section shaded in black represented coke formation on the metal surface

As aforementioned, the CH_4 is adsorbed and dissociated on the metal surfaces, forming H and CH_x intermediates. The H species can then recombine with another H species to form H_2 molecule. CO_2 is also activated on the metal surface by the formation of CO and surface O species, which react further with CH_x species to form CO molecule to inhibit the deposition of inactive coke on the metal surface. However, as the reaction proceeds, the active metal surface is covered with highly dehydrogenated carbon deposits, which eventually undergoes ageing and graphitization on the metal surface.²⁸ Thus, the increasing amount of carbonaceous residues continuously covered the active metal site for CH_4 and CO_2 activation, leading to an ongoing deactivation of DRM catalysts by coke deposition. The main steps are summarized as follows²⁸:

CH_4 and CO_2 activation on the metal surface:

On the other side, a bifunctional mechanism was proposed for the dry reforming reaction, in which the support participates in the reaction behavior. Lercher and his coworkers⁴⁶⁻⁴⁹ showed in a series of papers that the CO_2 molecule is predominantly adsorbed and activated on the support by the formation of carbonates. Other groups have shown the similar results of dry reforming over metal catalysts supported on Al_2O_3 ²⁸, La_2O_3 ⁵⁰, TiO_2 and MgO ^{51,52} that the support plays an important role in activating and converting CO_2 . The main mechanism are illustrated in Figure 1-9.

Figure 1-9. Schematic representation of dry reforming via a bifunctional mechanism. The section shaded in black represented coke formation on the metal surface. The surface oxygen species in the form of (hydrogen) carbonate was illustrated as O^* .

As mentioned above, the methane molecule is activated on the metal surface, forming H and CH_x species, which is similar as the mono-functional mechanism. Nevertheless, CO_2 is supposed to be adsorbed by the Lewis base center of the oxide support. The (hydrogen) carbonates formed during the CO_2 activation react subsequently at the interface between metal and support with the carbon species.

Thus, two reaction pathways exist in eliminating surface carbon species formed from methane decomposition, which is on the metal particles and on the boundary of metal and support. It is supposed that carbon removal reaction at the perimeter is much more faster than the carbon formation, while the carbon removal rate on the metal surface is lower than the CH₄ decomposition rate.⁴⁹ After a certain time, the metal surface was covered by a monolayer of coke to a large extent, but the perimeter is still available for the reaction. The main steps are summarized as follows²⁸:

CH₄ activation on the metal surface:

CO₂ activation on the support:

Hence, as discussed, Ni catalysts supported on oxide with higher concentration of oxygen vacancy and mobility of surface oxygen promote the removal of surface carbon deposition. In addition, the rate of carbon removal reaction increases with reducing metal particle size in terms of larger metal-support interface (shown in Scheme 1-10).

Figure 1-10. Schematic representation of influence of support and metal particle size on the coke formation during DRM reaction.

1.5. Catalysts for dry reforming of methane

A lot of studies have been dedicated to developing highly active and stable catalysts for DRM reaction, which include metal oxides, monometallic and bimetallic catalysts, and supported metal catalysts. Typically the DRM catalysts reported consist of a metal, i.e. Ni, Co, Ru, Rh, Pd and Pt, on an oxide support, such as SiO₂, Al₂O₃, MgO, TiO₂, CaO, CeO₂, ZrO₂ or La₂O₃.⁵³ These two components play an important role in the DRM reaction.³²

In general, the metal used for DRM reaction includes noble metals (Ru, Rh and Pt) and transition metals (Co and Ni). The catalyst based on noble metals are reported to have high catalytic activity and coke tolerance and excellent resistance towards agglomeration. Nevertheless, the high cost and low availability limits the industrial application of noble metal. Due to the lower price and higher availability, supported Ni catalysts have been widely investigated in recent research. However, compared to noble catalysts, nickel catalysts are generally more prone to form cokes under reaction condition and to sinter at high temperature.⁵⁴ Therefore, current focus of research is to improve the stability of DRM catalysts, with regard to different oxide support, preparation method, addition of promoter and bimetallic catalysts.

The oxide support itself is relatively catalytically inactive, however, there is strong evidence that the support have a significant effect on the stability of DRM catalyst. Bitter et al. reported the effect of Al₂O₃, ZrO₂ and TiO₂ and found that the stability of the catalysts increased in the order Pt/Al₂O₃ < Pt/TiO₂ < Pt/ZrO₂.⁵⁵ Zhang et al. also demonstrated the following influence of support on the initial DRM activity: Rh/ZrO₂ > Rh/TiO₂ ≅ Rh/Al₂O₃ > Rh/La₂O₃ ≈ Rh/SiO₂ > Rh/MgO.⁵⁶ Briefly, the support with a high oxygen storage capacity and mobility facilitate the carbon removal reaction, which leads to higher stability during DRM reaction.

In recent years, the addition of alkali and alkaline earth metals or metal oxide to enhance the activity and stability of DRM catalysts has also been investigated.³² Chang⁵⁷ et al. reported in 1996 that coke deposition on the catalysts was

remarkably eliminated by the addition of alkaline promoters such as K and Ca oxides, leading to the formation of carbonate species on alkaline promoters in the vicinity of Ni. Furthermore, the dissociative adsorption of CO₂ on the Ni surface was also facilitated with the addition of alkaline promoters. The addition of CaO also lead to an increased thermal stability. Dias and his coworker found that the impregnation of Ni and Ca on alumina increases the sintering resistance of the support and offer good catalytic performance during DRM reaction.⁵⁸ Pan et al. found that Ni/SiO₂-Ga₂O₃ catalyst showed a higher stability and coke resistance than the Ni/SiO₂ catalyst.⁵⁹ CO₂ is adsorbed physically onto SiO₂ and is activated on Ga₂O₃, resulting in surface carbonate and bicarbonate species, which react more easily with deposit carbon than reaction with linearly bonded or physically adsorbed CO₂.

CeO₂⁶⁰⁻⁶² was also suggested to be an efficient promoter for DRM catalysts. Ni catalysts with CeO₂ promoters reduced the chemical interaction between nickel and support, resulting in an increase in reducibility and higher dispersion of nickel particles. Beside, CeO₂ have high oxygen storage capacity (OSC), which provides positive effect on the activation of CO₂ during DRM, leading to an enhanced ability to remove coke in the vicinity of metal and support.

Additionally, instead of investigation of monometallic catalysts with various support modification, alloying with a second metal to form bimetallic catalysts have received much attention in recent years. The advantages of activity, selectivity and stability of the second metal was transferred on the first metal, leading to a modification of the catalyst properties through a synergistic effect between two metals.^{63,64} Frusteri et al. investigated potassium-promoted Ni/MgO catalyst in the dry reforming of methane.⁶⁵ Bare Ni/MgO system showed remarkable deactivation during DRM reaction in terms of sintering and formation of large amounts of whisker carbon. K addition lowered the reactivity of the catalyst, but, strongly improved its resistance to both coking and sintering processes. Osaki and Mori³⁸ concluded that K plays an important role in dividing the nickel surface into smaller ensembles, thus, suppressing carbon deposition.

Moreover, Chen et al. developed a long-term stable Cu-Ni/SiO₂ catalyst for CO₂ reforming of methane⁶⁶. They proved that the incorporation of Copper stabilized the structure of the active site on Ni surface for CH₄ decomposition and hindered the deactivation of the Ni catalyst caused by sintering or by loss of nickel crystallites. Lee et al. found that the addition of just 1% Cu could modify the Ni ensemble environment, resulting an enhanced stability for the DRM reaction.⁶⁷ Vanadium has also been investigated as promoter for DRM reaction.⁶⁸ It was found that the addition of V suppress the formation of NiAl₂O₄, which is inactive for DRM reaction. Tomishige et al. reported that the addition of Sn can effectively minimize carbon deposition.⁶⁹ The synergetic effect of Ni-Co based bimetallic catalysts also lead to highly active and stable reaction behavior.^{16,70-75} Alloying Ni with Co decreases the apparent Ni particle size to the size which is too small for carbon nucleation and growth.

1.6. Recent development in catalyst preparation methods

Recently, several innovative developments for the stabilization of supported nickel catalysts are reported. Most of them focus on the improved thermal stability at high reaction temperature and resistance to coke deposition during DRM reaction, including plasma treatment of Ni catalysts or stabilization of Ni nanoparticles within composite metal oxide, mesoporous structure and microporous zeolitic frameworks.

1.6.1. Plasma technology

In the last few years there has been an increasing use of plasma technology for catalyst synthesis as an improved resistance towards coke deposition.^{83,84} Compared to the conventional thermal method, the structure of the Ni nanoparticles can be easily controlled,⁸⁵ leading to an enhanced dispersion and surface concentration of the active metal phase. The energetic species in plasmas, electrons, ions and radicals can modify the metal particle size, morphology and metal-support interaction, leading to some specific catalytic properties.⁸⁶ In addition, the trace impurities in the gas stream, which is sensitive to the catalyst, can be also removed via plasma treatment.⁸⁷ Zhu et al. treated the Ni/Al₂O₃ with argon glow discharge plasma, displaying an excellent resistance to formations of filamentous carbon and encapsulating carbon for CO₂ reforming of methane than conventional thermally calcined Ni/Al₂O₃.⁸⁸ It was proved that the plasma treated Ni/Al₂O₃ has a high concentration of close packed plane and improved Ni dispersion.

Figure 1-11. Schematic representation of plasma treatment setup.⁸⁸

Wang et al. reported a similar preparation method using a plasma-assisted technique. Ni nanoparticles were confined within the pore channels of mesoporous Mg-SBA15.⁸⁹ It was proved that the plasma-treated catalyst exhibited a better stability against sintering than those of the untreated catalyst. In contrast to the calcined Ni catalyst, the plasma-treated catalyst showed excellent resistance to the deposition of filamentous carbon and encapsulating carbon. Similarly, this conventional treatment has been extended to synthesize Ni catalysts on various oxide supports, i.e. Ni/MgO⁷⁶ Ni/Al₂O₃-CeO₂⁷⁷ and Ni-Co/Al₂O₃-ZrO₂⁷⁸.

1.6.2. Stabilization of Ni nanoparticles within well-defined structure

Many recent investigations have been made to confine Ni particles in nickel precursors with well-defined structure. Halliche et al. investigated a series of Ni-based catalysts on HZSM-5 and USY zeolites, suggesting a better catalytic performance of Ni/USY than Ni/Al₂O₃.⁹⁰ Frontera et al. studied the influence of zeolite support on the overall catalyst performance. A high amount of silanol groups on the surface of silicalite-1 improve the CH₄ and CO₂ conversion but also reduce the deactivation of the catalyst due to coke deposition.⁹¹ However, in terms

of the requirement for operating at high temperature above 873 K, it is crucial to improve the thermal stability of the zeolite.⁹²

In another series of studies, nickel particles were stabilized on carbon/carbide support. Liu et al. reported a Ni containing mesoporous silica Ni-KIT-6, which was prepared by one-spot self-assembly method, resulting highly dispersed Ni species in the mesoporous silica (shown in Figure 1-12).⁹³ Compared with conventionally impregnated Ni catalysts, Ni-KIT-6 exhibits extremely smaller Ni particles and stronger interaction of Ni with silica matrix, which leads to high DRM activity and stability. Wang et al. also presented a one-pot evaporation-induced self-assembly method to synthesize mesoporous NiO-CeO₂-Al₂O₃ catalysts with high DRM stability.^{94,95}

Figure 1-12. Schematic diagram of the preparation of the Ni-KIT-6 catalyst.⁹³

Furthermore, Coperet and his coworkers published a versatile method for the preparation of small Ni nanoparticle through nickel–silicide colloid, with sizes of 1.3 ± 0.2 and 2.1 ± 0.2 nm (shown in Figure 1-13).⁹⁶ The resulting catalysts showed high activity in low temperature dry reforming reaction.

Figure 1-13. Conversion of nickel–silicide colloids into supported Ni catalysts and dry reforming reaction under its catalysis.⁹⁶

Recently, Han et al. reported highly coke-resistant Ni catalysts by immobilizing premade Ni nanoparticles onto functionalized silica supports.⁹⁷ The Ni/SiO₂ catalyst was then coated with silica overlayer, resulting a uniform distribution of Ni particles on the support (shown in Figure 1-14). The silica-coated Ni catalysts showed highly stable activity during 170 h of DRM reaction at 1073 K. In contrast, Ni catalysts without silica coating show severe sintering after DRM reaction, and the formation of filamentous carbon was observed.

Figure 1-14. DRM reaction over conventional supported Ni/SiO₂ and silica-coated nickel nanoparticle (NP) catalysts.⁹⁷

In this dissertation, we report a novel method to prepare small and well defined Ni nanoparticles supported on metal oxides under mild conditions. The synthesis of metal colloids uses metal salts (M^{n+}) as precursor, which are self-assembled in host molecular capsules to protect metal particles against sintering during calcination at high temperature, resulting metal particles with a size of 1-2 nm on the support.

Molecular capsules⁹⁸⁻¹⁰¹ formed via a spontaneous self-assembly process have been of great interest during the past decades. These capsule molecules consist of 6 resorcin[4]arene molecules connected via hydrogen bonds. The particularly interesting feature of these nanospheroid architectures for synthesis of catalytically active materials is the ability to encapsulate neutral and charged guest species within the well-defined cavity^{98,101} or to the formation of metal coordinated nanocapsules¹⁰². Thus, these structure can be regard as an ideal candidate for encapsulating positive charged metal ion. Zhang et al. reported that the resorcin[4]arene hexamer can encapsulate protonated tertiary amines which is used as an efficient enzyme-like catalyst for Wittig reaction.⁹⁹

Figure 1-15. Schematic representation of the hexameric resorcin[4]arene molecule and its self-assembly process to capsule molecule. The R group in red designates the alkyl group of resorcinarene molecule.

Furthermore, the size of a colloidal particles could be adjusted via modification of alkyl group of resorcinarene. Increasing the C number of the alkyl chain leads to an increased steric hindrance, which is more suitable for synthesis of well dispersed metal colloidal solution. In this dissertation, pyrogallol[4]arene molecule was used in the synthesis, leading to well-dispersed metal particles on the support after high temperature calcination and reduction.

1.7. Scope of this thesis

The main task of this dissertation is to differentiate between reactions on the metal surface and at the metal support interface during DRM and to use this knowledge for developing a new generation of highly active and stable catalysts. The insight required for designing catalysts includes the knowledge of the nature and geometrical properties of the metal particles and the way they are anchored to and interact with the support.

In the second chapter of this thesis, a detailed experiment study has been carried out to study the regeneration effect of CO₂ on the DRM reaction over Ni/ZrO₂ catalysts. Combining the experimental results from kinetic analysis, IR spectroscopy and XAS measurements under *operando* conditions, it was shown that after reduction the Ni particles were covered to a certain extent with partially reduced ZrO₂. The exposure to CO₂ at temperatures above 873 K resulted in the removal of the ZrO₂ decoration and additional sites for CO₂ activation at the interface between the support and the metal particles, thus enhancing the activity of the Ni/ZrO₂ catalysts for dry reforming of methane.

Based on the results described so far, it is evident that well dispersed on metal particles on a partially reducible support such as ZrO₂ will be essential to maintain the activity in the DRM reaction. Thus, in the following chapter, a new synthetic method via host colloidal solutions as metal precursors was shown to synthesize Ni and Pt catalysts. The particle sizes have been characterized by TEM and EXAFS measurements. The ZrO₂ supported Pt and Ni particles synthesized by this new method showed stable activities under DRM condition over a prolonged period. The amount of carbon deposition on the spent catalysts was quantified by the TGA measurement, indicating the same reaction rate of C-H bond activation (formation of CH_x species) and coke removal reaction. We proposed that the higher stability of these two catalysts is mainly due to the presence of small metal particles, which enlarges the metal-support interface and kinetically inhibits the deposition of inactive coke.

In the following discussion, two different pathways and active sites for H consumption was studied via the H₂ and H₂O formation. It is interesting to note that the H₂O formation is much more resistant against deactivation than H₂ formation on all catalyst for DRM reaction, which corresponds to the non-perimeter metal and perimeter metal. This allows us to monitor the catalyst deactivations for different active sites and reaction pathways. Furthermore, a H₂ and H₂O formation rate in a ratio of 2.5 ± 0.4 on Ni/ZrO₂ catalysts was observed under DRM condition, while on all other oxide supported catalyst the initial formation rate of H₂ was much higher, indicating the disbalance of the CH_x formation and coke removal reaction.

The final chapter concludes the summary and conclusion of this dissertation.

Chapter 2

Enhanced activity in methane dry reforming by CO₂ induced surface restructuring of Ni/ZrO₂

The activity of Ni/ZrO₂ catalysts for dry reforming of methane and its thermal stability are largely enhanced by activation and regeneration in presence of CO₂ above 873 K. After reduction in H₂, Ni particles are partly covered with Zr-suboxides. The exposure to CO₂ reduces this coverage and creates a larger ZrO₂-Ni interface. Being equilibrated with the metal surface, the Zr-suboxide acts as catalyst by accepting and later transferring one oxygen of CO₂ to the Ni surface, releasing CO in the decomposition of transiently formed carbonates. This leads to an additional channel of CO₂ dissociation in addition to the direct CO₂ dissociation on Ni. The higher, kinetically controlled availability of atomic oxygen on Ni is concluded to reduce the carbon concentration on the surface, leading to less refractory carbon deposition.

2.1. Introduction

Dry reforming of methane (DRM) leads to synthesis gas with H₂/CO ratios close to 1 and is frequently used to decrease this ratio in combined CH₄ reforming processes. To reach acceptable conversion levels, temperatures around 900 K are required.¹⁻⁵ Therefore, a significant challenge for the stability of reforming catalysts is to relieve sintering of the active metal.⁶ The other major challenge is to prevent coke deposition since the composition of reactants in dry reforming thermodynamically favors formation of carbon deposits.^{7,8}

To minimize sintering, metal particles have been stabilized on supports that prevent growth by limiting both transport of individual atoms, as well as coalescence of metal particles.^{5,9-15} In literature there is a controversial discussion on the role of the metal support interface on the activity and stability of a catalyst in dry reforming of methane. Iglesia et al. proposed that the activity is only related to the active metal and the particle size of the active metal, independent of the support.¹⁶⁻²⁰ Bitter et al. proposed a bifunctional pathway for dry reforming of methane over Pt/ZrO₂²¹⁻²⁸, where CO₂ is adsorbed and reacts in the vicinity of metal and support, whereas CH₄ is only decomposed at the metal surface. Therefore, they proposed that a catalyst is stable when the rates of CO₂ reduction and CH₄ activation are in balance. Montoya et al. used a Ce doped ZrO₂ support to demonstrate that the oxygen mobility at the metal support interface is crucial for a stable catalyst.²⁹ They have shown that the metal particles were partially covered with support under reducing conditions being therefore, not accessible for dry reforming.

As the ratio between carbon, oxygen and hydrogen in the feed gas allows carbon formation during methane dry reforming, the rate of carbon formation has to be minimized, either by limiting the formation itself via the synthesis and stabilization of nanoparticles^{9,12,13,15,30,31} or by preventing routes to form stable refractory carbon.^{5,13,29,32-34} Although great effort has been made in developing stable Ni

based dry reforming catalysts, carbon deposits still need to be removed periodically by oxidative treatments, which pose a challenge in itself, as the highly exothermic reaction with oxygen may lead to metal particle growth.

We report here a new approach overcoming above mentioned limitations via utilizing three principles of stabilizing catalysts for dry reforming. We combine (i) a lower rate of coke formation on a partially reducible support that (ii) stabilizes small metal particles with (iii) an endothermic, thermally less taxing regeneration of the coked catalyst. The combination of CO₂ as oxidant for carbon and of a support, which creates an active interface to the metal atoms and enables a more facile use of one of the oxygen atoms in CO₂ will be shown to combine high activity with high stability. Sites at the interface between Ni and the partially reduced Zr-support are the key for this additional pathway in methane dry reforming, providing oxygen for the reforming process itself as well as for regeneration of the coked catalyst. Oxygen vacancies at the interface between Ni and the ZrO₂ support will be shown to transiently convert CO₂ to carbonates, which in turn decompose, releasing CO and liberating one oxygen of the carbonate to diffuse to the metal surface and to regenerate the oxygen vacancy. Combining steady state and transient kinetic measurements with X-ray absorption spectroscopy the role of the individual steps of reactions for this new pathway will be elucidated.

Figure 2-1. Schematic representation of the DRM reaction over CO₂ treated Ni/ZrO₂ catalyst.

2.2. Experimental section

2.2.1. Chemicals

All chemicals were obtained from commercial suppliers and used as received. Nickel(II) nitrate hexahydrate (Sigma–Aldrich, ≥ 98.5%), zirconium hydroxide (Mel chemicals, XZO1501/03), silicon dioxide (Evonik, Aerosil 200), aluminum oxide (Evonik, Aeroxide AIUC)

2.2.2. Catalyst preparation

Zirconium hydroxide was calcined in air (flow rate 30 ml·min⁻¹) at 1073 K for 15 h with a heating rate of 0.5 K·min⁻¹. Ni-based catalysts supported on SiO₂, Al₂O₃ and ZrO₂ were prepared by incipient wetness impregnation using nickel(II) nitrate hexahydrate (Ni(NO₃)₂·6H₂O) as Ni precursor. Typically, Ni(NO₃)₂·6H₂O was dissolved in doubly distilled water to form a transparent green solution, and then the aqueous solution was slowly dropped onto support with continuous stirring at ambient temperature for 1 h. After impregnation at room temperature for further 20 h, the catalysts were dried at 373 K for 12 h. Afterwards, the catalyst was calcined in air at 673 K (heating rate 0.5 K·min⁻¹) for 2 h (flow rate 100 mL·min⁻¹) and reduced with pure H₂ at 873 K (heating rate 0.5 K·min⁻¹) for 2 h (flow rate 100 mL·min⁻¹).

2.2.3. Catalyst characterization

Elemental analysis was performed with atomic absorption spectroscopy (AAS) on a UNICAM 939 AA-Spectrometer. The BET specific surface area was determined from N₂ adsorption-desorption isotherms measured at 77 K on a PMI automatic BET-Sorptometer. Before measurement, the sample was activated in vacuum at 473 K for 2 h.

IR spectra of adsorbed CO was measured on a Bruker Vertex 70 spectrometer at a resolution of 4 cm⁻¹ collecting 128 scans in transmission absorption mode. The samples were pressed into self-supporting wafers and activated in flowing H₂ (p = 1 bar) at 923 K for 1 h (heating rate 10 K·min⁻¹) and then outgassed at 923 K for 0.5 h (p < 10⁻⁴ mbar) to remove H₂. After lowering the temperature to 313 K, the catalysts were exposed to CO (p = 5 mbar) for 0.5 h. Then, the catalysts were evacuated at 313 K for 30 min to remove the physically adsorbed CO. IR spectra of adsorbed CO on Ni/ZrO₂ were measured afterwards. Subsequently, Ni/ZrO₂ was treated in flowing CO₂ (p = 1 bar) at 923 K for 1 h, cooled to 313 K in CO₂ (p = 10 mbar). Then, the Ni/ZrO₂ catalyst was reduced in flowing H₂ (p = 1 bar) at 923 K for 1 h (heating rate 10 K·min⁻¹). After outgassing at 923 K for 0.5 h (p < 10⁻⁴ mbar), the temperature was lowered to 313 K. CO was adsorbed at 313 K with pressure of 5 mbar followed by evacuation. Afterwards, the IR spectra of adsorbed CO were recorded until no further changes in the spectra were observed.

2.2.4. Catalytic measurements

The catalytic activities of prepared catalysts (20 mg catalyst diluted in 480 mg SiC) were studied in a fix bed flow reactor at 873 K and atmospheric pressure. The catalysts were loaded in a quartz tube (7 mm diameter) and reduced in situ with 20 vol% H₂ in N₂ (total flow rate 100 mL·min⁻¹) at 873 K for 2 h. Then, the catalysts were heated to 1073 K in N₂ and the DRM reaction was carried out afterwards. The reactant gases consisted of 25 vol% CH₄ (99.995 vol%), 25 vol% CO₂ (99.995 vol%) and 50 vol% N₂ (99.999 vol%) with a total flow of 100 mL/min. N₂ was used as inert internal standard. The reaction products were analyzed online by Shimadzu GC-MS and GC fitted with TCD and FID. Reaction rate was expressed as methane consumption rate and calculated using following equations:

$$\text{Reaction rate} = \frac{\text{Conversion}_{\text{CH}_4} \times \text{CH}_4 \text{ in}}{n_{\text{Ni}}}$$

(Equation 2-1)

in which CH_{4 in} is the CH₄ amount in feed gas, and n_{Ni} is total amount of Ni on the catalysts. The conversion of CH₄ during DRM reaction was calculated as follows:

$$\text{Conversion}_{\text{CH}_4} = \frac{\text{CH}_4 \text{ in} - \text{CH}_4 \text{ out}}{\text{CH}_4 \text{ in}} \times \frac{N_2 \text{ in}}{N_2 \text{ out}} \times 100\%$$

(Equation 2-2)

in which CH_{4 out} is the CH₄ amount in outlet gas. The conversion of methane was normalized to the amount of N₂ in feed gas (N_{2 in}) and outlet gas (N_{2 out}).

The CO₂ regeneration reaction was carried out in situ at 1073 K. After 100 mins of DRM, the reaction was stopped and the catalysts were exposed to a stream of 100 % N₂ or CO₂ (flow rate 50 mL·min⁻¹) at 1073 K for 100 minutes. Subsequently, CH₄ and CO₂ were introduced into the reactor again and DRM reaction was produced directly after CO₂ regeneration. Two subsequent cycles of CO₂ treatment and DRM reaction were produced under the same condition, which was shown in Figure 2-2. The N₂ interruption test was carried out under the same condition by using N₂ instead of CO₂.

Figure 2-2. Schematic representation of in situ CO₂ regeneration and DRM reaction at 1073 K and atmospheric pressure.

2.3. Results and discussion

2.3.1. Deactivation of Ni/ZrO₂ catalyst

As aforementioned, the main problem for the DRM reaction is the deactivation of DRM catalysts caused by sintering of metal particles and coke formation.^{2-5,7} Thus, it is necessary to find out which factor is more essential for the stability of DRM catalysts. In view of this, a N₂ interruption test was planned to study the effect of sintering and coke formation on the reaction behavior. As shown in Figure 2-3(a), Ni/ZrO₂ catalyst showed decreased activity during 20 h of DRM reaction as the most DRM catalysts. A parallel experiment was carried out by treating the DRM catalyst with N₂ in situ at reaction temperature. As shown in Figure 2-3(b), after 100 minutes of DRM reaction the reaction was stopped and the catalysts were exposed to pure N₂ for 100 minutes. Thus, no DRM reaction was carried out during this period. After this step the rate on Ni/ZrO₂ did not decreased after switching back to reaction conditions, indicating the same amount of active site for dry reforming reaction. Two subsequent cycles with N₂ exposure followed by DRM reaction confirmed the unchanged concentration of surface nickel for methane activation during this N₂ treatment. Therefore, we concluded that no sintering occurred during this N₂ treatment at the temperature for DRM reaction. In contrast, as the DRM proceeds, Ni/ZrO₂ showed decreased activity, which is mainly due to the formation of inactive carbon species on the catalyst.

Figure 2-3. DRM rates for Ni/ZrO₂ (Zr8SNi17) at 1073 K at atmospheric pressure without interruption (a) and with N₂ interruption (b). The catalysts were treated in 100 % N₂ in the sections indicated. (c) Plots of DRM rates for Ni/ZrO₂ without interruption (green) and with N₂ interruption (orange) by excluding the section of N₂ treatment.

To further explain the unchanged DRM reactivity of Ni/ZrO₂ catalyst during N₂ treatment, Figure 2-3 (b) was rearranged to exclude the section of N₂ treatment. It is interesting to note that the pattern of CH₄ consumption rate with TOS during DRM reaction were almost identical over N₂ treated and non-treated Ni/ZrO₂ (as shown in Figure 2-3 (c)), which further proved that sintering at high reaction temperature has almost no effect on the deactivation of Ni/ZrO₂ during DRM reaction. As a consequence, formation of inactive coke during DRM reaction was proved to be the critical reason for the deactivation of Ni/ZrO₂ catalyst. For this reason, we focused on the removal of inactive carbon and in situ regeneration of ZrO₂ supported nickel catalyst in the following chapter.

2.3.2. In situ activation and stabilization of Ni/ZrO₂ with CO₂.

Coke deposition on the DRM catalysts can be removed via oxidative treatment using O₂, H₂O and CO₂.³⁵ However, compared to CO₂ and H₂O, treating Ni catalyst with O₂ at high temperature also lead to sintering of nickel particles. Thus, in this work, Ni/ZrO₂ was regenerated with CO₂ in situ under DRM condition at 1073 K, which showed increased DRM activity after CO₂ treatment.

The turnover rates for CH₄ conversion on ZrO₂ supported Ni catalysts at 1073 K are shown as a function of time on stream in Figure 2-4. In the first 100 minutes these three Ni/ZrO₂ catalysts showed relatively lower DRM activity. After 100 minutes, the reaction was stopped and the catalysts were exposed to a stream of 100 % CO₂ at 1073 K for 100 minutes. After this step the rate on all Ni/ZrO₂ increased markedly after switching back to reaction conditions. The Zr8SNi17 (1.18 wt% Ni/ZrO₂ synthesized by sol gel method) and Ni/ZrO₂ had initial DRM activities of 2.43 and 1.59 mole_{CH₄} s⁻¹ mole_{Ni}⁻¹, which increased to 3.43 and 3.24 mole_{CH₄} s⁻¹ mole_{Ni}⁻¹, respectively (shown in Figure 2-4 (a) and (b)). The Zr8Ni1imp (1 wt% Ni/ZrO₂ synthesized by incipient wetness impregnation) exhibits the strongest CO₂ regeneration effect among these three Ni/ZrO₂ catalysts, which increased from 0.38 to 2.76 mole_{CH₄} s⁻¹ mole_{Ni}⁻¹ (shown in Figure 2-4 (c)). Two subsequent cycles with intermediate CO₂ exposure followed by DRM reaction confirmed the re-activation of the Ni/ZrO₂ catalyst.

Figure 2-4. DRM rates for (a) Zr8SNi17 (1.18 wt% Ni/ZrO₂ synthesized by sol gel method), (b) 1 wt% Ni/ZrO₂ and (c) Zr8Ni1imp (1 wt% Ni/ZrO₂ synthesized by incipient wetness impregnation). The catalysts were treated in 100 % CO₂ in the sections indicated.

To test the stability of the CO₂ treated catalyst, a reaction with longer TOS was carried out with 1 wt% Ni/ZrO₂. After 100 min of DRM at 1073 K, Ni/ZrO₂ was treated with CO₂ for 100 min and the activity for DRM was monitored for 130 h. As shown in Figure 2-5, the initial reaction rate of methane was 1.59 mol_{CH₄} mol_{Ni}⁻¹ s⁻¹ and decreased to 0.97 mol_{CH₄} mol_{Ni}⁻¹ s⁻¹ after 100 min of DRM. After CO₂ treatment it increased to 3.24 mol_{CH₄} mol_{Ni}⁻¹ s⁻¹. During the following 130 h of reaction time the reaction rate decreased to 2.12 mol_{CH₄} mol_{Ni}⁻¹ s⁻¹, which was still above the initial activity before CO₂ activation.

Figure 2-5. DRM rates over a 1% Ni/ZrO₂ during a long term test. The catalysts were treated in 100 % CO₂ in the section shaded in grey for 100 min.

2.3.3. Reaction parameters for in situ activation by CO₂.

The changes in the activity demonstrate that Ni/ZrO₂ underwent a chemical or physical transformation by exposure to CO₂. Thus, Pt/ZrO₂ was treated with CO₂ under the same conditions to study the effect of metal on the *in situ* activation. As shown in Figure 2-6, Pt/ZrO₂ showed decreased activity in the first 100 minutes of DRM reaction. Afterwards, Pt/ZrO₂ was treated with pure CO₂ at 1073 K for 100 minutes. However, compared to ZrO₂ supported nickel catalysts, the DRM activity of Pt/ZrO₂ did not increase after CO₂ treatment. Two further in situ CO₂ treatment followed by DRM reaction confirmed that the DRM activity of Pt/ZrO₂ would not be affected by the CO₂ treatment.

Figure 2-6. DRM rates for Pt/ZrO₂. The catalyst was treated in 100 % CO₂ in the sections indicated.

SiO₂ and Al₂O₃ were also included in this work to demonstrate the effect of support on the CO₂ regeneration. The turnover rates for CH₄ conversion on Ni supported on SiO₂, Al₂O₃ and ZrO₂ at 1073 K are shown as a function of time on stream in Figure 2-7. In the first 100 minutes the rates on the three catalysts were similar. At this point, the reaction was stopped and the catalysts were exposed to a stream of 100 % CO₂ at 1073 K for 100 minutes. After this step the rate on Ni/ZrO₂ increased markedly. It is important to emphasize that for Ni/Al₂O₃, the exposure to CO₂ did not affect the course of deactivation, while Ni/SiO₂ was strongly deactivated. Two subsequent cycles with CO₂ exposure followed by DRM demonstrate that periodical reactivation of Ni/ZrO₂ with CO₂ restitutes the activity of Ni/ZrO₂. It is interesting to note that treatment with CO₂ at 1073 K before DRM increased the reaction rate to the level it reached otherwise after regeneration, i.e., it increased by somewhat less than a factor of three for Ni/ZrO₂. Exposure to He at 1073 K did not affect the activity.

Figure 2-7. DRM rates for (■) Ni/ZrO₂, (●) Ni/Al₂O₃, (▲) Ni/SiO₂ and (▼) CO₂ treated Ni/ZrO₂ at 1073 K before reaction. The catalysts were treated in 100 % CO₂ in the sections indicated. The dotted red line designates the initial reaction rate for CH₄ decomposition at 1073 K.

To differentiate between a chemical reaction of CO₂ with the catalyst and the removal of coke by oxidation, the Ni/ZrO₂ catalyst was treated with O₂ (10 vol% O₂ in N₂) instead of CO₂ between two DRM reaction cycles (as shown in Figure 2-8). In contrast to the CO₂ treatment, the DRM activity did not increase after O₂ treatment as if the DRM reaction would have continued, which can be attributed to a combined effect of coke removal and metal sintering during O₂ treatment. This was also confirmed by a control experiment using O₂ as regeneration gas and the catalyst was treated with CO₂ directly after DRM reaction over O₂ treated Ni/ZrO₂ (as shown in Figure 2-8). The similar initial activities after CO₂ and O₂ treatment

suggested that CO₂ treatment did not change the particle size of Ni on the ZrO₂. Note that during the treatment with CO₂, the oxidation of previously formed carbon deposits as well as that of the metal particles is endothermic (Table 2-1), while the oxidation with oxygen is highly exothermic. Hence, compared to O₂, CO₂ is regarded as a mild oxidizing and regeneration agent.

Figure 2-8. DRM rates over a 1% Ni/ZrO₂. The catalysts were treated in situ at 1073 K with 100 % CO₂ or 10 % O₂ in N₂ in the sections indicated.

Table 2-1. Reaction equations and corresponding reaction enthalpies for different oxidation reactions of Ni and carbon.

| | | |
|----|---|---|
| 1. | $\text{CO}_2 + \text{C} \rightleftharpoons 2\text{CO}$ | $\Delta H^0 = 169.9 \text{ kJ mol}^{-1}$ |
| 2. | $\text{Ni} + \text{CO}_2 \rightleftharpoons \text{NiO} + \text{CO}$ | $\Delta H^0 = 47.1 \text{ kJ mol}^{-1}$ |
| 3. | $\text{C} + \text{O}_2 \rightleftharpoons \text{CO}_2$ | $\Delta H^0 = -394.8 \text{ kJ mol}^{-1}$ |
| 4. | $2\text{Ni} + \text{O}_2 \rightleftharpoons 2\text{NiO}$ | $\Delta H^0 = -235.2 \text{ kJ mol}^{-1}$ |

Additionally, the effect of partial pressure of CO₂ during regeneration on the in situ activation was directly observed by flushing the Ni/ZrO₂ catalyst with different concentration of CO₂ in the gas phase. As shown in Figure 2-9, exposing the catalyst during the break in reaction with 5 vol% CO₂ did not affect the course of deactivation. Notably, treating Ni/ZrO₂ with 100 vol%CO₂ led to a strong increase of the activity of Ni/ZrO₂. Thus, the re-activation cannot happen during reaction due to a too low partial pressure of CO₂.

Figure 2-9. Regeneration as a function of CO₂ partial pressure: (a) 5 vol% CO₂ in N₂ for 20 min, (b) 5 vol% CO₂ in N₂ for 40 min, (c) 100 % CO₂ for 20 min and (d) 100 % CO₂ for 40 min.

To further study the influence of the temperature on the in situ activation, the initial activities of CH₄ during DRM reaction were measured over CO₂ treated and untreated Ni/ZrO₂ between 823 and 1073 K. Firstly, Ni/ZrO₂ was in situ reduced in H₂ at 873 K and then the temperature was changed to the reaction temperature. Afterwards, DRM reaction and CO₂ regeneration were produced at the same temperature. As shown in Figure 2-10(a), the exposure of Ni/ZrO₂ to CO₂ at 823 K did not affect the reaction activity, while the initial activities of Ni/ZrO₂ increased after CO₂ treatment at temperature above 873 K. In addition, CO₂ treated nickel catalysts shows more stable reaction behavior in comparison with dry reforming over untreated nickel catalysts, indicating the stabilization and maintenance of the reaction activity after treating with CO₂.

Figure 2-10. DRM rates over a 1% Ni/ZrO₂. The catalysts were treated in situ at (a) 823 K, (b) 873 K, (c) 923 K, (d) 973 K, (e) 1023 K and (f) 1073 K, with 100 % CO₂ in the sections indicated. The DRM reactions were carried out at the same temperature as the temperature for CO₂ treatment.

Furthermore, it is interesting to note that the difference of DRM activities before and after CO₂ regeneration become larger with increasing CO₂ treatment temperatures. The reaction rate and the ratio of initial DRM rate before and after CO₂ treatment was illustrated in Figure 2-11. At 823 K and 873 K, a comparable DRM reactivity before and after CO₂ treatment were observed, while above 873K the differences increased remarkably with increasing temperature. The results further demonstrated that high temperature facilitate the effect of CO₂ regeneration.

Figure 2-11. Initial DRM rate over 1 wt% Ni/ZrO₂ catalysts before (orange) and after (blue) CO₂ treatment. The green dot indicate the ratio of initial DRM activities over 1 wt% Ni/ZrO₂ catalysts before and after CO₂ treatment.

2.3.4. Mechanism of in situ activation by CO₂ regeneration.

It would be conceivable that the increase in the DRM rate after exposure to CO₂ is associated with the formation of smaller Ni particles formed during exposure to CO₂. As observed by Gonzalez, the exposure of a Ni/ZrO₂ catalyst to CO at high temperature increases the dispersion of the nickel metallic phase.³⁶ According to the DRIFTS results, Ni(CO)₄ complexes were formed via CO treatment, which corrodes the nickel particles and deposit nickel particles onto ZrO₂. Consequently, the size of nickel particles decreased after CO treatment. In our previous work, we have proved that CO₂ could be dissociated on Pt/ZrO₂, releasing oxygen and CO.²⁴ Thus, this leads us to hypothesize that CO plays a role in activation of Ni/ZrO₂ for DRM reaction.

For this reason, a control experiment with CO treatment was carried out at 1073 K, in which the Ni/ZrO₂ catalyst was treated with 20 vol% CO in N₂ and 100 % CO (total flow rate 100 mL·min⁻¹) at 1073 K for 100 min directly after DRM reaction (shown in Figure 2-12). Nonetheless, the reaction activity did not change after in situ CO treatment under the same condition as the CO₂ treatment. Thus, the enhanced DRM activity would not be caused by the increases of nickel dispersion via Ni(CO)₄. Moreover, further treatment of Ni/ZrO₂ with pure CO₂ after 600 minutes of DRM lead to an enhanced reaction activity (as shown in Figure 2-14), with an identical reaction rate (3.29 mol_{CH₄} mol_{Ni}⁻¹ s⁻¹) as the rate after CO₂ regeneration. Consequently, we can exclude that the particle size of metallic nickel is affect by the CO treatment.

Figure 2-12. DRM rates over a 1% Ni/ZrO₂. The catalysts were treated in situ at 1073 K with 20 vol% CO in N₂, 100 % CO and 100 % CO₂ in the sections indicated, respectively.

The perfect linearity of the Arrhenius plot in Figure 2-13 shows that for both CO₂ treated and untreated catalyst DRM follows the same mechanism over the whole temperature range.⁷ As it has been paradigmatically stated in literature^{19,37,38} that C-H activation is rate determining, the identical activation energies of 89 and 85 kJ/mol for CO₂ treated and untreated Ni/ZrO₂ proof that the overall mechanism of methane dry reforming is not affected by the CO₂ treatment. The increase of the pre-exponential factor by 2.5 times, indicates that a higher concentration of metal sites was available for CH₄ conversion in the reactor after exposure to CO₂.

Figure 2-13. Arrhenius plots for dry reforming over CO₂ (●) treated and (◻) untreated Ni/ZrO₂.

In order to independently determine the concentration of sites at the metal support interface we turn to IR spectroscopy of adsorbed CO (Figure 2-14 and Table 2A-1). The bands of adsorbed CO above 2000 cm⁻¹ are typical for linearly bonded CO on Ni.³⁹ The shoulder observed above 2100 cm⁻¹ is attributed to CO adsorbed on partially oxidized Ni.^{39,40} In accordance to Goodman et al., we assign the band at 2085 cm⁻¹ to CO adsorbed on Ni at the metal-support interface.⁴¹ Note that this allows in principal to differentiate the undisturbed sites on the metal surface (bands below 2075 cm⁻¹) and sites in vicinity of the ZrO₂ support (band at 2085 cm⁻¹). After the CO₂ treatment, the intensity of the sum of the bands attributed to Ni surface sites increased 2.9 times (assuming that the adsorption coefficient of CO on Ni was identical in the two measurements), while the band at 2085 cm⁻¹ increased nearly by a factor of 2. Most importantly the use of CO as probe molecule shows that the corresponding sites on Ni, i.e. the Ni sites adjacent to a defect vary in concentration exactly in proportion to the increase in rate of oxidation of Ni by CO₂ and the increase in rate of CO₂ reduction during DRM.

Figure 2-14. IR spectra of CO adsorbed at 5 mbar followed by evacuation on the untreated (a) and CO₂ treated (b) Ni/ZrO₂ catalyst.

The almost identical value of H₂/CO ratio before and after CO₂ regeneration over the whole temperature range further indicated the improved ability to resist coke formation. As shown in Figure 2-15, the initial H₂/CO ratios did not change after treating the Ni catalysts with CO₂ over the temperature range between 823 K and 1073 K. As aforementioned, the total amount of Ni surface sites increased 2.9 times after CO₂ treatment, indicating an enhanced CH_x and H formation rate (via CH₄ decomposition reaction). Thus, the rate of H₂ formation increased via recombination of H species. However, the ratio of H₂/CO did not change, suggesting that the rate of coke removal reaction by the formation of CO also increased after CO₂ activation. Consequently, the CO₂ treated Ni/ZrO₂ catalysts did not show an increased deactivation rate in spite of the increased amount of surface Ni species for CH₄ activation.

Figure 2-15. Ratio of initial H₂:CO value over 1 wt% Ni/ZrO₂ catalysts before and after CO₂ treatment.

The increased support metal interface was further proved by EXAFS measurement, which was carried out by my coworker Matthias Steib. The results showed that after reduction in H₂, Ni particles are partly covered with Zr-suboxides.⁴²⁻⁴⁷ The exposure to CO₂ reduces the coverage by Zr-suboxides⁴⁸ and creates a larger ZrO₂-Ni interface, which is consistent with the result that H₂/CO ratio was not changed after CO₂ treatment. Being equilibrated with the metal surface, the Zr-suboxide acts as catalyst by accepting and later transferring one oxygen of CO₂ to Ni surface releasing CO in the decomposition of transiently formed carbonates. This leads to an additional channel of CO₂ dissociation in addition to the direct CO₂ dissociation on Ni. The higher kinetically controlled availability of atomic oxygen on Ni is hypothesized to reduce the carbon concentration on the surface, leading to less refractory carbon deposition.^{35,49,50}

2.4. Conclusions

We have shown that exposure of Ni/ZrO₂ to CO₂ at high temperatures enhances the activity of the catalysts for DRM as well as the rate of oxidation of reduced Ni particles. The proposed reaction mechanism is illustrated in Figure 2-16. The increase in rate has been associated with a higher concentration of accessible Ni metal sites, while the stability is provided by the labile atomic oxygen being able to oxidize surface carbon formed during the dissociation of methane. The formation of this labile oxygen occurs through transiently formed carbonates at the metal support interface, which increases at the same time the fraction of accessible Ni surface sites. In DRM, this effect causes the approximately three-fold higher rate of CO formation by providing additional oxygen to remove carbon formed by the rate determining CH₄ dissociation. During regeneration the availability of oxygen via this route leads to the formation of CO via the (endothermic) Boudouard reaction, which is not as taxing with respect to heat evolution than the more conventional (exothermic) regeneration with O₂. While the nature of the ZrO₂ species at the Ni particles cannot be deduced from the current experiments, all observations are consistent with the fact that treatment with CO₂ maximizes the accessible ZrO₂ - Ni boundary as well as the concentration of metal surface sites. Overall, the results show that (inexpensive) Ni can be successfully used as catalyst in methane dry reforming, when ZrO₂ is used as support, generating a highly dynamic catalyst, which restructures itself during catalysis and regeneration by CO₂ on a nanoscopic level.

Figure 2-16. Schematic representation of the elementary steps during CO₂ treatment.

2.5. Associated Content

Publication

This chapter is based on the article of the same title as appeared to be submitted in *Angewandte Chemie*. The content and structure of Chapter 2 is different from this manuscript.

Contributions

Yu Lou did the main contributions in experimental design, kinetic experiments, IR spectroscopy, data analysis and manuscript preparation. Matthias Steib contributed with all EXAFS measurements, data analysis and manuscript preparation. Anita Horvath is responsible for the synthesis of Ni catalysts named Zr₈SNi₁₇ and Zr₈Ni₁imp. Andreas Jentys supervised the topic of CO₂ regeneration and was responsible for data analysis and manuscript preparation. Johannes A. Lercher is the principal investigator of this work.

Acknowledgments

This work was financially supported by the European Union under project ERA Chem and the BMBF under the project ZeitKatMat. The X-Ray absorption experiments were performed on the SuperXAS beamline at the Swiss Light Source, Paul Scherrer Institut, Villigen, Switzerland and at the CLAESS beamline at ALBA Synchrotron with the collaboration of ALBA staff. The authors gratefully acknowledge the beamline scientists Maarten Nachtegaal and Laura Simonelli for their help during the beamtime.

Chapter 3

Stable Nickel based catalysts for dry reforming of methane

Novel approaches to synthesize highly dispersed nickel particles on ZrO₂ led to catalysts, which are active and stable for dry methane reforming. Successful catalysts had a particle size of around 1 nm and were stable against sintering and extensive carbon formation. Such catalysts had a H₂ and H₂O formation rate in a ratio of 2.5 ± 0.4 , while on all others the initial formation rate of H₂ was much higher. On all but the stable Ni/ZrO₂ catalysts, deactivation of H₂ formation was much faster than that of H₂O formation. At longer time on stream the ratio of H₂ and H₂O formation rate was 2.5 ± 0.4 for all the Ni/ZrO₂ catalyst, no matter if they were stable from beginning or after deactivating to a stable level. At higher values, the catalyst underwent severe deactivation. We conclude that H₂ is formed on all surface Ni, while H₂O is preferentially formed close to the Ni-ZrO₂ interface only. As small Ni nanoparticles as observed for 1 wt% Ni/ZrO₂ contained a high fraction of all accessible Ni close to the Ni-ZrO₂ interface, the catalysts was highly stable.

3.1. Introduction

In recent years there has been growing interest in dry reforming reaction, which utilize the greenhouse gases, i.e. CH₄ and CO₂, to produce synthesis gas with H₂/CO ratio close to one^{1,2}. Typical catalysts for this reaction include VIIIA metals and noble metals on oxide support. However, supported VIIIA metals catalysts for DRM, i.e. Ni and Co, suffer from strong deactivation as a result of metal sintering and coke deposition under H₂O free reaction conditions.^{1,2} The excess rate in the reaction forming surface carbon (Equation 3-1) to the reaction removing surface carbon species (Equation 3-2) was found to be the reason for the coke deposition.

(Equation 3-1)

(Equation 3-2)

In our previous work³ we have identified two reaction pathways for activating CO₂, i.e. on the metal particle and on the boundary between perimeter metal and support. The activation of CO₂ on the boundary is fast enough to transfer O onto the perimeter Ni which removes the surface carbon generated from CH₄ activation, forming CO. While the CO₂ activation on the metal surface is, however, much slower than the carbon deposition from CH₄. Thus, the utilization of transition metal oxides as support, i.e. ZrO₂³⁻¹⁰ and CeO₂¹¹⁻¹⁴, have been extensively investigated to improve reactivity and stability due to the higher oxygen storage capacity on these oxide supports. In chapter 2, we have further proved the importance of the Ni-ZrO₂ perimeter in activating CO₂ during DRM reaction, which facilitates the CO₂ activation at the interface between Ni and ZrO₂ and kinetically inhibit the deposition of coke. Furthermore, it is interesting to note that the H₂O formation is much more resistant against deactivation than H₂ formation, indicating two different pathways

and active sites for H₂O and H₂ formation. This, consequently, leads to a continuously decreasing ratio between H₂ and H₂O with TOS during DRM reaction, and allow us to monitor the catalyst deactivations for different active sites and reaction pathways.

Figure 3-1. Rate of H₂ (orange) and H₂O (green) formation over a Ni/ZrO₂* catalyst at 1073 K during DRM reaction. Interval is treatment under 100 % CO₂ at 1073 K to regenerate catalyst by coke removing. *The catalyst was synthesized by conventional incipient wetness impregnation with metal loading of 1 wt%.

As shown in Figure 3-1, DRM over Ni/ZrO₂*, represented by the formation of H₂ and H₂O, underwent deactivation with TOS due to coke deposition on the catalyst. The rate decreased sharply for H₂ formation, suggesting the largely decreased number of accessible surface Ni (SNi) for both methane activation and H₂ formation (Equation 3-3).

(on the SNi) (Equation 3-3)

In contrast, the rate for H₂O formation was much more stable compared to that of H₂ formation. In particular, removing the surface cokes via reverse Boudouard reaction under CO₂ (Equation 3-4), the H₂ formation activity was largely recovered while H₂O formation rate was unaffected. This result indicates that H₂ formation over Ni/ZrO₂ in DRM occurs on Ni sites that easily blocked by cokes while H₂O formation takes place dominantly on a different site that is hardly affected by cokes.

(Equation 3-4)

The formation of H₂ takes place via the association of two H atoms on surface Ni (Equation 3-3), while the formation of H₂O requires an additional O atom, which is supplied by dissociation of CO₂.

Figure 3-2. Schematic representation of perimeter Nickel (P Ni) and non-perimeter Nickel (NP Ni).

Thus, the evolution pattern of the H₂O formation rate with TOS is explained by the decreased number of surface Ni for CO₂ activation in the initial stage (Equation 3-5(a)) and a stable supply of oxygen via CO₂ activation on the Ni-ZrO₂ perimeter (Equation 3-5(b)).

(on the NP Ni (minority)) **(Equation 3-5a)**

(on the P Ni (majority)) **(Equation 3-5b)**

Therefore, supported metal particles with smaller particle size provide larger metal-support interface and higher fraction of perimeter Ni, and thus promotes the removal of surface carbon species in the DRM reaction. To reduce the metal particle size after calcination and reduction at high temperature, various methods¹⁵⁻²² have been dedicated to the design of metal catalysts with encapsulated structures. However, these methods require complicated synthesis procedures and rigorous preparation conditions during the synthesis and, therefore, synthesis of well dispersed metal nanoparticles with sizes down to nanometer scale, i.e. 1 nm, for DRM reaction is still a challenge.

In this context, we report a novel method to prepare small and well defined Ni nanoparticles supported on metal oxides under mild conditions. The synthesis of metal colloids uses metal salts (Ni^{2+}) as precursor, which are self-assembled in host capsules²³⁻²⁶ to protect metal particles against sintering during calcination at high temperature. Ni catalysts synthesized by this new method showed small particle sizes on the support after calcination and reduction at high temperature. The 1 wt% Ni/ZrO₂ was found to be resistant to coke deposition during DRM in terms of larger Ni-ZrO₂ interface, which exhibits extremely high stability during DRM reaction.

3.2. Experimental and theoretical methods

3.2.1. Chemicals

All chemicals were obtained from commercial suppliers and used as received. Ni(II) nitrate hexahydrate (Sigma–Aldrich, $\geq 98.5\%$), zirconium hydroxide (Mel chemicals, XZO1501/03), silicon dioxide (Evonik, Aerosil 200), aluminum oxide (Evonik, Aeroxide AIUC), chloroform (CHCl_3) solution (Sigma, $\geq 99.9\%$)

3.2.2. Catalyst preparation

Zirconium hydroxide ($\text{Zr}(\text{OH})_4$) was calcined in air (flow rate $30 \text{ ml}\cdot\text{min}^{-1}$) at 1073 K for 15 h with a heating rate of $0.5 \text{ K}\cdot\text{min}^{-1}$. Ni based catalysts supported on SiO_2 , Al_2O_3 and ZrO_2 were prepared using nickel colloidal solution as metal precursor. At first, H_2O saturated CHCl_3 solution was prepared by dropping H_2O into CHCl_3 and mixed by sonication as described in detail previously²⁶. Then pyrogallol[4]arene was added into organic phase, forming a clear solution after gentle heating. Subsequently, $\text{Ni}(\text{NO}_3)_2\cdot 6\text{H}_2\text{O}$ was added in the host molecule solution and the solution was stirred overnight until all $\text{Ni}(\text{NO}_3)_2\cdot 6\text{H}_2\text{O}$ was dissolved. After a period of 20 h, the oxide support was added in the nickel colloidal solution before evaporation under reduced pressure. Afterwards, the as-prepared catalyst was dried at 373 K for 12 h, air-calcined at 673 K (heating rate $0.5 \text{ K}\cdot\text{min}^{-1}$) for 2 h (flow rate $100 \text{ mL}\cdot\text{min}^{-1}$) and reduced in pure H_2 at 873 K (heating rate $0.5 \text{ K}\cdot\text{min}^{-1}$) for 2 h (flow rate $100 \text{ mL}\cdot\text{min}^{-1}$).

3.2.3. Catalyst testing

DRM reactions were carried out in a fix bed reactor. Typically, 50 mg of catalysts were diluted with 450 mg SiC. The catalyst sample was loaded in a quartz reactor (7 mm diameter) and reduced with 20 vol% H_2 in N_2 (total flow rate $100 \text{ mL}\cdot\text{min}^{-1}$) at 873 K for 2 h before DRM. Afterwards, 25 vol% CH_4 (99.995 vol%), 25 vol%

CO₂ (99.995 vol%) and 50 vol% N₂ (99.999 vol%) with a total flow of 100 mL/min were introduced into the reactor and the DRM reaction was carried out at the same temperature and atmospheric pressure. N₂ was used as calibration standards. The amount of reaction products were determined online by Shimadzu GC-MS and GC, using TCD and FID as detector. Conversion and reaction rate of methane were calculated via aforementioned equation (2-1) and equation (2-2), respectively:

$$\text{Reaction rate} = \frac{\text{Conversion}_{\text{CH}_4} \times \text{CH}_4 \text{ in}}{n_{\text{Ni}}}$$

(Equation 2-1)

$$\text{Conversion}_{\text{CH}_4} = \frac{\text{CH}_4 \text{ in} - \text{CH}_4 \text{ out}}{\text{CH}_4 \text{ in}} \times \frac{N_2 \text{ in}}{N_2 \text{ out}} \times 100\%$$

(Equation 2-2)

3.2.4. Catalyst characterization

The elemental composition of Ni was measured by atomic absorption spectroscopy (AAS) on a UNICAM 939 AA-Spectrometer. The BET specific surface area was determined by nitrogen adsorption-desorption isotherms measured at 77 K on a PMI automatic BET-Sorptometer. The sample was activated in vacuum at 473 K for 2 h prior to the measurement.

Transmission electron microscopy (TEM) images were taken by a JEM-2010 Jeol transmission microscope operating at 120 kV. The sample was firstly made suspension in ethanol by ultrasonication, and a drop of such suspension was deposited onto a carbon-coated Cu grid.

X-ray absorption measurements were performed at the Super XAS beamline at the SLS in Villigen, Switzerland recorded at the with a channel-cut Si(111) monochromator.²⁷ Data analysis was carried out with Athena and Artemis software from the IFEFFIT²⁸ package and with FEFF6.²⁹

The amount of coke deposits on spent catalysts were quantified by thermogravimetric analysis (TGA) on a SETARAM Sensys Evo system. For these experiments, 10 mg of spent catalysts (SiC free) were loaded in the sample holder. The samples were pretreated in He (flow rate 16 mL·min⁻¹) at 473 K (heating rate 10 K·min⁻¹) to remove adsorbed H₂O and CO₂ before cooling to 303 K. Subsequently, the temperature was increased to 1073 K (heating rate 5 K·min⁻¹) in air (flow rate 16 mL·min⁻¹) and kept for 0.5 h. The amount of coke deposition were obtained from the weight loss of the spent catalysts.

¹H-NMR spectra were recorded at 500 MHz, using a Bruker AV 500 spectrometer. ¹H-NMR chemical shifts are given in ppm by using CHCl₃ as references (7.26 ppm).

3.3. Results and discussion

3.3.1. Estimation of particle size threshold for stable DRM catalysts

The fraction of perimeter nickel in total number of surface nickel as a function of Ni nanoparticle size was estimated using a hemispherical-shaped model for Ni nanoparticles on the ZrO_2 . As shown in our previous work, CO_2 is activated at the oxygen vacancies at the interface between Ni and ZrO_2 to form surface oxygen species in the form of transient carbonates (Figure 3-3).³⁻⁷

Figure 3-3. Schematic representation of the carbonate formation in the vicinity of Ni and ZrO_2 over DRM catalysts with metal particle size of 0.75 nm

This oxygen is on top of one interface Ni and can react with H or C atoms on its closest adjacent Ni, therefore the surface Ni in the bottom layer, i.e. the layer at Ni- ZrO_2 interface, and in the second layer from the bottom are accessible to oxygen from CO_2 and both are considered as perimeter Ni. Consequently, all the nickel atoms are perimeter Ni when the particle size is below 1 nm (Figure 3-3), while a fraction of the surface Ni was in the third layer from the bottom thus not accessible to oxygen when the particle size is above 1 nm (Figure 3-4).

Figure 3-4. Schematic representation of the carbonate formation in the vicinity of Ni and ZrO₂ over DRM catalysts with metal particle size of 1.25 nm

Therefore, we hypothesize that the fractions of perimeter remains 1.0 for the Ni particles with size below 1 nm, however above this threshold this fraction decreased sharply with growing particle size (Figure 3-5). The above calculations show that an ideal Ni/ZrO₂ catalyst for DRM must have Ni particle size of below 1 nm on which every Ni is at the perimeter interface, where the CO₂ activation is faster than surface carbon formation, thus having a very slow coke deposition rate during DRM reaction.

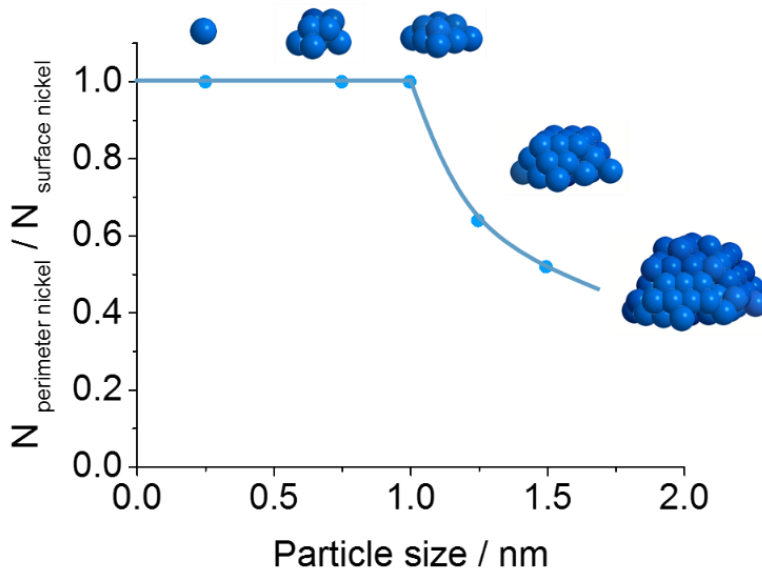

Figure 3-5. Estimation of impact of particle size on the fractions of perimeter nickel in total number of surface nickel.

3.3.2. Synthesis of small nickel and platinum particles via metal colloidal solution

To synthesize nano-sized nickel particles on oxide supports, a novel method using nanocapsules is presented in this work. The compound rccc-5,11,17,23-tetrahydroxy-2,8,14,20-tetra(n-ndecyl)resorc[4]arene (pyrogallol[4]arene) was synthesized according to a literature procedure^{30,31}, its structure was confirmed by NMR spectroscopy. The Ni colloid was prepared by adding Ni(NO₃)₂·6H₂O into a water saturated chloroform (CHCl₃) solution (Sigma, ≥ 99.9 %) and mixing by sonication as described in detail previously²⁶. After 1 h the solution was added to pyrogallol[4]arene yielding a clear solution after gentle heating. The synthesis strategy is shown in Figure 3-6. The long alkyl chains on the outer surface of nanocapsules provide a large distance between the capsules and metal ions, which is essential for the stability towards aggregation in the colloidal solution and allows to achieve a good dispersion of Ni²⁺ in the precursor solution. The encapsulation of the Ni²⁺ ions by the host molecules was confirmed by the absence of unsolved metal salts in the synthesis mixture after overnight stirring (shown in Figure 3-6).

In a control experiment, Ni(NO₃)₂·6H₂O was added into the water saturated CHCl₃ solution without pyrogallol[4]arene, which led to sedimentation of Ni salt as it is not soluble in the organic phase. Furthermore, by the increase of the Ni concentration in the water saturated CHCl₃ solution from 3 mg/L to 71 mg/L after adding pyrogallol[4]arene confirmed the encapsulation of Ni²⁺.

Figure 3-6. Encapsulation of Ni^{2+} during synthesis procedure with hexameric pyrogallolarene capsule.³²

To investigate the location of Ni^{2+} in the metal-organic nanocapsule, increasing amounts of $\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ were added to the hexameric pyrogallol[4]arene solution. The concentration of Ni species in the organic phase was measured by atomic absorption spectroscopy (AAS), showing an increasing amount of Ni species in the hexameric pyrogallol[4]arene solution from 71 mg/L to 365 mg/L (Table 1), while the nickel concentration did not change in the pure $\text{H}_2\text{O}/\text{CHCl}_3$ solution. This result indicated the transfer of Ni species from solid state to organic solution, which could be explained by the encapsulation of Ni^{2+} in the arene capsule or coordination of Ni^{2+} with pyrogallol[4]arene via Ni-O bonds.

Table 3-1. Concentration of Ni species in the water saturated CHCl_3 solution with increasing amount of $\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ before and after involving pyrogallol[4]arene molecule. Ethanol was added to the capsule solutions to destruct the host molecules and Ni species was extracted with water before AAS measurement.

| n ($\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$) : n (capsule molecule) | 0 | 1 | 2 | 5 |
|---|---|-----|-----|-----|
| C_{Ni} in the $\text{H}_2\text{O}/\text{CHCl}_3$ (mg/L) | - | 3.3 | 3.3 | 3.4 |
| C_{Ni} in the capsule solution (mg/L) | - | 71 | 150 | 365 |

According to the published literature, 2 possible structures of Ni colloidal molecule could be presented after encapsulating Ni species. Zhang et al. reported that cationic guests are bound inside the cavity via cation- π interactions (shown in Figure 2-7 (a)).²⁶ On the other side, metal ions insert into the hydrogen-bonding networks and substitute H_2O molecules by the formation of metal coordinated capsule molecule based on the same structural motif, which offers greater stability rigidity (shown in Figure 2-7 (b)).³³

Figure 3-7. Schematic representation of possible structures of capsule molecule by the addition of metal salt in the host solution. (a) Cationic guests are encapsulated in the cavity²⁶ and (b) metal coordinated capsule molecule³³.

Hence, the total concentration of encapsulated CHCl_3 molecules in the cavity was determined from ^1H NMR spectra (Table 2 and Figure 3A-1). After adding $\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, the number of encapsulated CHCl_3 (integral intensity of the H signal at 4.5ppm) did not decrease, suggesting that CHCl_3 inside the cavity were not replaced by other guest species (Ni^{2+} or NO_3^-). Note that the integral intensity of the peaks did not change, while the width of the peak increased from 0 to 5 eq, which could be explained by the faster relaxation of nearby protons after coordination with paramagnetic metal ion (Ni^{2+}).³⁴

Table 3-2. Integral of the encapsulated CHCl_3 peaks with increasing amount of $\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$. The integral of the methanetriyl group (3.84 ppm, 24 H) of the assembly of pyrogallol[4]arene were used as references to determine the encapsulation ratio.

| n ($\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$) : n (capsule molecule) | 0 | 1 | 2 | 5 |
|---|-------|-------|-------|-------|
| Integral of encapsulated CHCl_3 protons | 10.09 | 10.24 | 10.80 | 10.16 |

Hence, Ni species were concluded to be located on the surface of the capsule molecules, which substitute H_2O molecules and insert into the hydrogen-bonding networks by the formation of Ni-O bonds. Compared to hydrogen bonded capsules on the same structural motif²⁴, the metal coordination increases the stability and rigidity of the structure.

In order to gain more insight into the structure of the nickel-organic nanocapsules during the synthesis procedure, *in situ* XAFS experiments at the Ni K-edge were carried out (Figure 3-7). ZrO_2 was used as support due to its higher oxygen storage capacity¹. However, Ni/ZrO_2 could not be analyzed by XAFS due to the high

absorption cross section of the support³⁵, therefore, SiO₂ supported Ni catalysts were used as model catalysts for further XAS experiments. The strong white line at ca. 8350 eV confirmed the presence of oxidized Ni on the dried and *in situ* calcined samples. After reduction with H₂ at 873 K for 90 minutes, Ni was fully reduced, confirmed by the absence of the white line at 8350 eV in the XANES of Ni (Figure 3-8).

Figure 3-8. XANES at the Ni K-edge of dried (green), calcined (blue) and in situ reduced (orange) 1 wt% Ni/SiO₂.

The analysis of the EXAFS (Figure 3-9 and Table 3A-1) revealed the presence of Ni-O contributions and the absence a metallic Ni environment in the dried sample, which is in agreement with the formation of a nickel-organic nanocapsule via Ni-O coordinative bonds. After reduction an average coordination numbers for

Ni-Ni of 5.53 was observed for Ni/SiO₂, which indicates the presence of Ni particles with an average size of 1.1 nm³⁴.

Figure 3-9. Fourier transformed EXAFS at the Ni K-edge recorded at room temperature 1 wt% Ni/SiO₂ after drying under vacuum at room temperature (blue line), *in situ* oxidation (orange line) and *in situ* reduction (green line). The dotted lines are the results of the EXAFS fits.

3.3.3. Characterization of particle size

The TEM pictures of the catalysts are shown in Figure 3-10. This method was also extended to Pt and Ni/Pt bimetallic catalysts. Note that TEM images do not allow to differentiate the Ni and the ZrO₂ due to the low difference in the contrast³⁶. The average metal particle sizes of supported catalysts synthesized using metal colloidal precursors were below 2 nm. Therefore, long alkyl chains on the outer surface of these capsules provide large distances between each capsule and metal species and prevent metal-to-metal contact and reduce the tendency for sintering during calcination^{15,37}, which leads to small mean particle size after high temperature treatment.

Figure 3-10. TEM images of reduced catalysts. (a) 1 wt% Ni/SiO₂ (b) 1 wt% Pt/ZrO₂ (c) 1 wt% Ni/ZrO₂ (d) 1 wt% Pt/ZrO₂ (e) 1 wt% NiPt/SiO₂ (f) 1 wt% NiPt/ZrO₂

To explore the influence of nickel loading on the final particle size, EXAFS of 1 wt%, 2 wt% and 5 wt% Ni/SiO₂ were analyzed after drying and *in situ* reduction (Figure 3-11 and table 3A-2). For the dried samples, Ni was present in oxidized form (as concluded above from the XANES) with the same coordination number (~4.7) for the three samples. After *in situ* reduction, the disappearance of the Ni-O contributions and a contraction of the Ni-Ni distances were observed. The 1 wt% Ni/SiO₂ showed the lowest Ni-Ni coordination number within these three catalysts, with Ni particle size of 1.1 nm. This is consistent with the results of TEM microscopy, taking into consideration the increases of molar volume upon oxidation.¹⁵

The nickel particle size of 2 wt% and 5 wt% Ni/SiO₂ are 1.5 and 1.9nm, respectively, which reveals that the concentration of Ni inside the nanocapsule determines the size of the final Ni particle on the support. We further assume that the nickel particles have the same size on the SiO₂ and ZrO₂ as Ni/ZrO₂ could not be analyzed by XAFS due to the high absorption cross section of the support³⁵

Figure 3-11: Fourier transformed EXAFS at the Ni K-edge recorded at room temperature of dried (a) and reduced (b) 1 wt% Ni/SiO₂ (blue line), 2 wt% Ni/SiO₂ (orange line) and 5 wt% Ni/SiO₂ (green line). The dotted lines are the results of the EXAFS fits.

3.3.4. Catalytic performance

The catalytic activities of Ni and Pt supported on ZrO_2 are shown in Figure 3-12. ZrO_2 supported Ni and Pt catalysts showed slight deactivations in the first 100 mins of reactions, followed by stable activities during further 3000 mins of DRM. In addition, the H_2/CO ratio remained constant over an extended reaction time, which indicates that the rate of carbon formation reaction is kinetically equal to the rate of carbon removal.

Figure 3-12. Reaction rate of CH₄ (Δ) and H₂/CO ratio (\circ) over (a) Pt/ZrO₂, (b) Ni/ZrO₂ at 873 K during DRM reaction.

The stable activities during DRM reaction were also consistent with the almost identical amount of coke deposited on the catalysts after a short period of DRM reaction. TGA measurements of spent catalysts after DRM reaction are shown in Figure 3-13. The amount of carbon deposition on the spent catalysts remained constant after 100 and 200 mins over Ni/ZrO₂ and Pt/ZrO₂ respectively, indicating that the rate of C-H bonds activation (formation of CH_x species) and coke removal via oxygen species (in form of carbonate) are equal. This results is consistent with our previously work showing that coke removal is carried out at the Pt-ZrO₂ perimeter³ and small metal particle sizes enlarge the metal-support interface and could, thus, kinetically inhibit the deposition of inactive coke^{4,5,8} on the catalysts, leading to stabilization of metallic catalysts under DRM condition.

Figure 3-13. Total amount of coke accumulation over (a) Pt/ZrO₂, (b) Ni/ZrO₂ during DRM reaction.

3.3.5. Influence of particle size on the DRM activity and stability

The catalytic activities of the ZrO₂ and SiO₂ supported Ni catalysts for methane dry reforming are shown as the conversion rate of CH₄ in Figure 3-14. All the three Ni/ZrO₂ catalysts showed comparable initial rate per surface Ni, (0.63 ± 0.09) mol_{CH₄} s⁻¹ mol_{Ni}⁻¹, regardless of the Ni loading. The Ni/SiO₂ catalyst was the least active, with an initial rate of 0.19 mol_{CH₄} s⁻¹ mol_{Ni}⁻¹. However, 1 wt% Ni/ZrO₂ was much more stable against deactivation compared to other catalysts. During the first 200 minutes of reaction the 1 wt% Ni/ZrO₂ catalyst showed only a slight deactivation, followed by a period of 1000 mins with constant activity. In contrast, the catalysts with 2 and 5 wt% Ni on ZrO₂ (nanocapsule/Ni(NO₃)₂·6H₂O = 1:2 and 1:5) suffered from a fast and continuous deactivation during DRM reaction, which led to a loss of activity of 71 % and 84 % after 900 minutes, respectively. The 1 wt% Ni/SiO₂ showed the strongest deactivation, which led to an almost complete loss of activity after 50 min TOS.

Figure 3-14 Reaction rate of CH₄ over (a) 1 wt% Ni/ZrO₂, (b) 2 wt% Ni/ZrO₂ (c) 5 wt% Ni/ZrO₂ and (d) 1 wt% Ni/SiO₂ at 873 K during DRM reaction.

The pattern of H₂ and H₂O formation rate with TOS during DRM reaction were shown in Figure 3-15, which decreased sharply for H₂ formation on 2 wt% and 5 wt% Ni/ZrO₂, while the rate was relatively stable on the 1 wt% Ni/ZrO₂ over a long period of time. This agrees well with the decreases in the CH₄ conversion activities (on the surface Nickel, S_{Ni}) over these 3 catalysts, suggesting the largely decreased number of accessible surface Ni on 2 wt% and 5 wt% Ni/ZrO₂ for methane activation. In contrast, the rate for H₂O formation was much more stable on all catalysts compared to H₂ formation rate.

Figure 3-15. Rate of H₂ (orange) and H₂O (blue) formation over (a) 1 wt% Ni/ZrO₂, (b) 2 wt% Ni/ZrO₂ and (c) 5 wt% Ni/ZrO₂ at 873 K during DRM reaction.

To monitor the changes of active sites on DRM catalysts under DRM reaction conditions, we further compared the evolution of the rates of H₂O and H₂ formation with time on stream. The ratio between H₂ and H₂O formation rate over Ni/ZrO₂ catalysts at 873 K were shown as a function of time on stream in Figure 3-16. It is seen that the Ni/ZrO₂ catalysts had different initial $r_{\text{H}_2} / r_{\text{H}_2\text{O}}$ values, e.g. 2.56 on 1 wt% Ni/ZrO₂, 5.30 on 2 wt% Ni/ZrO₂ and 6.27 on 5 wt% Ni/ZrO₂, which, however, approached and stabilized at the same level (2.5 ± 0.4) after a certain time on stream. This is further shown on two stable Ni/ZrO₂ catalysts (Zr6Ni3imp (2.7 wt% Ni/ZrO₂) and Zr82Ni3imp (3 wt% Ni/ZrO₂)) synthesized by impregnation with the concomitant addition of NaHCO₃ published in our previous work.³⁸ It is noteworthy

that all the stable catalysts (1 wt% Ni/ZrO₂, Zr₆Ni₃imp and Zr₈₂Ni₃imp) showed an initial $r_{\text{H}_2} / r_{\text{H}_2\text{O}}$ value already around 2.5. This allows us in principal to differentiate the metal surface sites both undisturbed (NP Ni), which is far from the interface between Ni and ZrO₂ and have no reactive atomic oxygen transferred from the support, and in vicinity of the ZrO₂ support (perimeter Ni, P Ni). Here we assign this number ($r_{\text{H}_2} / r_{\text{H}_2\text{O}} = 2.5$), based on the results from our previous work, to the quantitative selectivity ratio between H₂O and H₂ formed on the perimeter Ni as the non-perimeter nickel (NP Ni) was completely covered by the coke deposition after deactivating to a stable level.³

Figure 3-16. (a) ratios of H₂ and H₂O formation rate over (■) 1 wt% Ni/ZrO₂, (●) 2 wt% Ni/ZrO₂, (▲) 5 wt% Ni/ZrO₂, (▼)Zr₆Ni₃imp and (◆)Zr₈₂Ni₃imp at 873 K during DRM reaction. (b) Initial (orange) and stable (blue) ratios of H₂ and H₂O formation rate over these Ni/ZrO₂ catalysts and 1 wt% Ni/SiO₂. The green horizontal bar in Figure (a) and (b) represents the interval of r_{H_2} / r_{H_2O} value under steady state.

Thus, as summarized in Figure 3-17, the Ni/ZrO₂ catalysts with an initial r_{H_2} / r_{H_2O} value of 2.5 showed much more stable DRM activities compared to the DRM over Ni/ZrO₂ catalysts with higher initial r_{H_2} / r_{H_2O} value. The Ni/SiO₂ showed the highest r_{H_2} / r_{H_2O} ratio and relatively lower reaction rate, which is due to the strongest deactivation in the initial reaction.

Figure 3-17. Rate of H₂ formation in the initial state (orange) and under stable condition (green) and rate of H₂ formation in the initial state (blue) and under stable condition (red).

As discussed, H₂ formation was formed on atomic nickel via dissociative adsorption of CH₄, forming surface C and H. In the absence of O, H leaves the surface via formation of H₂ while C accumulates and forms coke. With the accessibility to O, H and C could leave the surface in the form of H₂O and CO, thus coke formation and deactivation is alleviated. This means that the ratio of r_{H_2} / r_{H_2O} indicates the deficiency of surface O, and correlates with catalyst deactivation. Thus, we can use this value to estimate the DRM stability of ZrO₂ supported nickel

catalysts. The relation between deactivation rate and r_{H_2} / r_{H_2O} number are plotted in Figure 3-18. The deactivation rate of DRM catalysts is defined as

$$\text{Deactivation rate} = \frac{dr_{CH_4}}{d(TOS)} \times \frac{1}{r_{CH_4}}$$

(Equation 3-6)

It is remarkable that the deactivation rate increased exponentially with the r_{H_2} / r_{H_2O} ratio, which we assigned to the faster rate in forming surface carbon (Equation 3-1) than that removing the surface carbon (Equation 3-2), which lead to an accumulation of carbon deposits on the Ni and finally to cokes. This positive correlation indicates importance of perimeter nickel in the DRM reactions, which increases the rate of delivering surface oxygen to surface carbons, preventing coke formation.

Figure 3-18. Deactivation rate against r_{H_2} / r_{H_2O} ratio over (■) 1 wt% Ni/ZrO₂, (●) 2 wt% Ni/ZrO₂, (▲) 5 wt% Ni/ZrO₂, (▼)Zr6Ni3imp, (◆)Zr82Ni3imp and (■)1 wt% Ni/SiO₂ at 873 K during DRM reaction.

To quantitatively explain the stable activity of the 1 wt% Ni/ZrO₂ catalyst during DRM, the fractions of perimeter nickel in total number of surface nickel was quantified by the H₂ formation rate on the two types of Ni sites. The initial rate of H₂ formation on perimeter nickel $r(\text{initial H}_2)_{(P\ Ni)}$ was calculated using Equation 3-7:

$$r(\text{initial H}_2)_{(P\ Ni)} = r(\text{initial H}_2O)_{(P\ Ni)} \times 2.5$$

(Equation 3-7)

in which $r(\text{initial H}_2O)_{(P\ Ni)}$ is the initial rate of H₂O formation on perimeter nickel and an unchanged selectivity ratio of 2.5 between H₂O and H₂ formed on the nickel-ZrO₂ perimeter in the initial stage of reaction and under steady state is assumed. The $r(\text{initial H}_2O)_{(P\ Ni)}$ was calculated using Equation 3-8:

$$r(\text{initial H}_2O)_{(P\ Ni)} = r(\text{initial H}_2O)_{(S\ Ni)} - r(\text{initial H}_2O)_{(NP\ Ni)}$$

(Equation 3-8)

in which $r(\text{initial H}_2O)_{(S\ Ni)}$ is the overall H₂O initial formation rate obtained in DRM reaction, and $r(\text{initial H}_2O)_{(NP\ Ni)}$ is the rate contributed by NP Ni which was measured from the activity of the Ni/SiO₂ catalysts since CO₂ activation was not facilitated on the SiO₂ and thus gives the lower boundary for the rate in absence of the sites at the Ni-ZrO₂ perimeter.

Thus, the fractions of NP Ni to P Ni can be represented by their individual contribution in H₂ formation rate which is by the following expression

$$\frac{r(\text{initial H}_2)_{(NP\ Ni)}}{r(\text{initial H}_2)_{(P\ Ni)}} = \frac{r(\text{initial H}_2)_{(S\ Ni)} - r(\text{initial H}_2)_{(P\ Ni)}}{r(\text{initial H}_2)_{(P\ Ni)}}$$

(Equation 3-9)

Eventually, this fraction is calculated using the Equation 3-10 after rearrangement of Equation 3-9.

$$\frac{r(\text{initial H}_2)_{(\text{NP Ni})}}{r(\text{initial H}_2)_{(\text{P Ni})}} = \frac{r(\text{initial H}_2)_{(\text{S Ni})} - [r(\text{initial H}_2\text{O})_{(\text{S Ni})} - r(\text{initial H}_2\text{O})_{(\text{NP Ni})}] \times 2.5}{[r(\text{initial H}_2\text{O})_{(\text{S Ni})} - r(\text{initial H}_2\text{O})_{(\text{NP Ni})}] \times 2.5}$$

(Equation 3-10)

The fraction of H₂ formed on the NP Ni to that on P Ni was found to be dependent on the particle size (Figure 3-19), which decreased with reducing particle size. Therefore, a particle size threshold of 1 nm was found in the DRM reaction, below which all the surface nickels were on the perimeter thus no undisturbed nickel existed. As reported in our previous work,³ the activation of CO₂ on the support is fast enough to remove surface carbon in the vicinity of perimeter. Thus, the 1 wt% Ni/ZrO₂ showed stable reactivity during DRM because of its small Ni size (1.1 nm). However, for 2 and 5 wt% Ni/ZrO₂, due to the larger Ni particle size, the disbalance between the reaction forming surface carbon and the reaction removing it leads to the coke accumulation and catalyst deactivation during DRM reaction. This is supported by the higher amount of coke on the spent catalysts with larger Ni particle size (Figure 3-19). All observations are consistent with the fact that nickel particles with size below 1 nm kinetically inhibit the formation of coke on the DRM catalysts.

Figure 3-19. Amount of coke deposition (orange) and ratio of initial H₂ formation on the NP Ni to that on the P Ni (green) over 1 wt% Ni/ZrO₂, 2 wt% Ni/ZrO₂ and 5 wt% Ni/ZrO₂ at 873 K during DRM reaction.

3.4. Conclusions

The new synthesis method developed based on encapsulating Ni particles into molecular capsules via a spontaneous self-assembly process allows preparation of Ni/ZrO₂ catalyst with small to 1.1 nm particle size. In this approach the long alkyl chains on the outer surface of host capsules increase the distance between each capsule and the nickel ions, leading to a stabilization of nickel particles during calcination and reduction at elevated temperature. The smallest Ni particle size on 1 wt% Ni/ZrO₂ makes all the surface Ni on the perimeter interface, where Ni were highly accessible to surface O generated by CO₂ activation on the interface ZrO₂. This leads to a decrease of H₂ to H₂O ratio in the products and a faster removal of surface C via CO formation, and consequently a slow rate in coke formation and high stability against deactivation. Large Ni particles contains a lower fraction of perimeter nickel species, thus a deficiency in accessibility to O, making higher H₂ to H₂O and slower surface carbon removal, leading to a fast deactivation.

3.5. Associated Content

Publication

This chapter is based on the article of the same title as appeared which is prepared to be submitted. The content and structure of Chapter 3 is different from this manuscript.

Contributions

Yu Lou did the main contributions in experimental design, kinetic experiments, catalysts preparation, data analysis and manuscript preparation. Matthias Steib contributed with all EXAFS measurements. Anita Horvath is responsible for the synthesis of 2 stable Ni catalysts named Zr₆Ni₃imp and Zr₈₂Ni₃imp. Qi Zhang contributed with synthesis of pyrogallol[4]arene molecule. Andreas Jentys and Yue Liu supervised the topic of catalysts synthesis and kinetic measurements and was responsible for data analysis and manuscript preparation. Johannes A. Lercher is the principal investigator of this work.

Acknowledgments

This work was financially supported by the European Union under project ERA Chem and the BMBF under the project ZeitKatMat. The X-Ray absorption experiments were performed on the SuperXAS beamline at the Swiss Light Source, Paul Scherrer Institut, Villigen, Switzerland. The authors gratefully acknowledge the beamline scientists Maarten Nachtegaal and Ola Safonova for their help during the beamtime.

Chapter 4

Summary and Conclusions

The aim of this thesis is to elucidate and understand the elementary reactions of DRM and to use this knowledge in developing highly active and stable catalysts for DRM. Two strategies were applied in this thesis, both focusing on improving the stability of the catalysts against coke formation via enhancing the supply of reactive oxygen species to remove coke from the metal surface.

In the first approach N₂ interruption test is applied to study the effect of coke deposition on the stability of DRM catalyst. Sintering of nickel particles has only slight effect on the reaction behavior, while the accumulation of inactive coke plays a role in the stability of DRM catalysts.

Then, we have studied the effect of nature and geometrical properties of metal particles and their interaction with the support on the dry reforming of methane (DRM) activity. The activity of Ni/ZrO₂ catalysts for DRM can be significantly enhanced and catalyst's thermal stability can be improved by activation and regeneration in presence of CO₂ above 873 K. After reduction in H₂, Ni particles are partly covered with Zr-suboxides. The exposure to CO₂ reduces the coverage by Zr-suboxides and creates a larger ZrO₂-Ni interface. Thus, compared to the direct CO₂ dissociation on metallic nickel, CO₂ treatment leads to an additional channel of CO₂ dissociation in addition to the direct CO₂ dissociation on Ni. The higher kinetically controlled availability of atomic oxygen on Ni is hypothesized to reduce the carbon concentration on the surface, leading to less refractory carbon deposition. In comparison to exposure to O₂, CO₂ treatment leads to a fast, but thermally less taxing oxidation of carbon deposits.

In the second approach, two pathways for H reactions were observed on ZrO₂ supported nickel catalysts, corresponding to the recombination of H species on metal surface to form H₂ and reaction of H species with surface oxygen species at the interface between Ni and ZrO₂ to form H₂O. It was shown that H₂ formation over Ni/ZrO₂ in DRM occurs on metallic Ni surface that easily blocked by cokes

while H₂O formation takes place dominantly on a different site that is hardly affected by cokes.

Subsequently, particle size threshold for stable DRM catalysts was estimated using hemispherical-shaped model. We hypothesize that the fractions of perimeter remains 100 % for the Ni particles with size of 1 nm. The carbon removal reaction can be thus facilitated by decreasing metal particle size.

Using this knowledge, a strategy was developed to synthesize stable catalysts for DRM reaction. The new method uses Ni and Pt colloids as metal precursor on a metal-oxide as support. Ni and Pt particles with size of 1-2 nm were dispersed on SiO₂, Al₂O₃ and ZrO₂. ZrO₂ supported Ni and Pt catalysts exhibited stable activities for more than 2 days of DRM reaction at 873 K, with only small amounts of coke deposited on the catalysts. ZrO₂ supported metal catalysts with small particle sizes, which have large metal-support interface, kinetically inhibit the deposition of inactive coke and allow to stabilize the catalysts during the DRM reaction.

Finally, the particle size threshold for stable DRM catalysts was proved by kinetic measurements. 1 wt% Ni/ZrO₂ has nearly 100 % of perimeter nickel and metallic nickel was highly accessible to surface O generated by CO₂ activation, leading to a fast removal of carbon deposition in the vicinity of Ni and ZrO₂.

Overall, the results show that (inexpensive) Ni can be also successfully used as catalyst in methane dry reforming, when metallic nickel are well dispersed on oxide supports with high oxygen storage capacity and oxygen species mobility.

In the future, we would like to further improve these methods to meet the requirement for industrial application including higher reaction temperature and pressure. Furthermore, combination of these two methods to synthesize a CO₂ treated catalyst with small metal particles to reach a higher activity and stability is under development.

Chapter 5

Zusammenfassung und Folgerungen

Das Ziel dieser Arbeit ist es, die Elementarreaktionen von DRM aufzuklären und zu verstehen und anhand der erworbenen Erkenntnisse hochaktive und stabile Katalysatoren zu entwickeln. In dieser Arbeit wurden zwei Strategien angewendet, die sich beide auf die Verbesserung der Stabilität der Katalysatoren gegen die Koksbildung durch die Erhöhung der Zufuhr von reaktiven Sauerstoffspezies zur Entfernung von Koks auf der Metalloberfläche konzentrieren.

Im ersten Ansatz werden N₂-Unterbrechungstests angewandt, um den Einfluss der Koksablagerung auf die Stabilität des DRM-Katalysators zu untersuchen. Das Sintern von Nickelpartikeln hat nur eine geringe Auswirkung auf das Reaktionsverhalten. Die Anreicherung von inaktivem Koks spielt eine wichtige Rolle für die Stabilität von DRM-Katalysatoren.

Wir haben die Auswirkung der Beschaffenheit und Form der Metallpartikel und ihrer Wechselwirkung mit dem Träger auf die Aktivität der Trockenreformierung (DRM) untersucht. Die Aktivität und die thermische Stabilität des Ni/ZrO₂-Katalysators für DRM kann durch Aktivierung und Regeneration in Gegenwart von CO₂ bei einer Temperatur von über 873 K signifikant gesteigert und verbessert werden. Nach der Reduktion in H₂ werden die Ni-Partikeln teilweise mit Zr-Suboxiden bedeckt. Die CO₂-Behandlung reduziert die Bedeckung mit Zr-Suboxiden und führt zur einer größeren ZrO₂-Ni-Grenzfläche. Im Vergleich zur direkten CO₂-Dissoziation auf metallischem Nickel eröffnet die CO₂-Behandlung zu einem zusätzlichen Reaktionspfad der CO₂-Dissoziation über Ni. Es wird vermutet, dass die höhere kinetisch gesteuerte Verfügbarkeit von atomarem Sauerstoff auf Ni die Kohlenstoffkonzentration auf der Oberfläche reduziert, was zu weniger Kohlenstoffablagerungen führt. Im Vergleich zur Einwirkung von O₂ führt die CO₂-Behandlung zur einer schnellen, aber thermisch weniger strapazierenden Oxidation von Kohlenstoffablagerungen.

In einem weiteren Ansatz werden zwei Reaktionspfade für den Wasserstoffverbrauch auf ZrO₂-geträgerten Nickelkatalysatoren beobachtet, die der Rekombination von H-Spezies auf der Metalloberfläche unter Bildung von H₂

und der Reaktion der H-Spezies mit Oberflächen-Sauerstoffspezies an der Grenzfläche zwischen Ni und ZrO_2 unter Bildung von H_2O entsprechen. Es wurde gezeigt, dass die H_2 -Bildung auf Ni/ ZrO_2 , die auf der metallischen Ni-Oberfläche auftritt, leicht durch Koks blockiert wird. Jedoch Die H_2O -Bildung erfolgt hauptsächlich an anderen Zentren, die kaum von Koks beeinflusst werden.

Anschließend wurde der Schwellenwert der Teilchengröße für stabile DRM-Katalysatoren unter Verwendung eines hemisphärischen Modells abgeschätzt. Wir nehmen an, dass der Anteil von Ni an der Grenzfläche 100 % beträgt, wenn die Ni-Partikelgröße einen Wert von 1 nm nicht überschreitet. Die Entfernung von Kohlenstoff kann somit durch die Verringerung der Metallpartikelgröße erleichtert werden.

Anhand dieser Erkenntnisse wurde eine Strategie entwickelt, um stabile Katalysatoren für die DRM-Reaktion zu synthetisieren. Die neue Methode verwendet Ni und Pt-Kolloide als Metallvorläuferverbindungen, die auf einem Metalloxid geträgert wurden. Ni und Pt-Partikeln mit einer Größe von 1-2 nm wurden auf SiO_2 , Al_2O_3 und ZrO_2 dispergiert. ZrO_2 -geträgerte Ni und Pt-Katalysatoren zeigten eine stabile DRM-Aktivität bei 873 K für mehr als 2 Tage, wobei nur geringe Mengen von Koks auf den Katalysatoren abgeschieden wurden. ZrO_2 -geträgerte Metallkatalysatoren mit kleinen Teilchengrößen und einer großen Metall-Träger-Grenzfläche inhibieren die Abscheidung von inaktivem Koks kinetisch und ermöglichen die Stabilisierung der Katalysatoren während der DRM-Reaktion.

Schließlich wurde der Schwellenwert der Partikelgröße für stabile DRM-Katalysatoren durch kinetische Messungen nachgewiesen. Wenn der Anteil an Nickel an der Grenzfläche zwischen Ni und ZrO_2 100 % beträgt, ist das metallische Nickel für die Oberflächensauerstoffspezies, die durch die Aktivierung von CO_2 erzeugt wurde, sehr gut zugänglich, was zu einer schnellen Entfernung der Kohlenstoffablagerung in der Umgebung von Ni und ZrO_2 führt.

Insgesamt zeigen die Ergebnisse, dass (kostengünstiges) Ni auch erfolgreich als Katalysator in der Methan-Trockenreformierung eingesetzt werden kann, wenn metallisches Nickel fein dispergiert auf Oxidträgern mit hoher Sauerstoffspeicherkapazität und hoher Mobilität der Sauerstoffspezies vorliegt.

In Zukunft möchten wir diese Methoden weiter verbessern um den industriellen Anforderungen einschließlich höhere Reaktionstemperatur und –druck gerecht zu werden. Weiterhin befindet sich eine Kombination dieser beiden Methoden zur Synthese eines mit CO₂ behandelten Katalysators mit kleinen Metallpartikeln in der Entwicklung um eine höhere Aktivität und Stabilität zu erreichen.

Curriculum Vitae

Name: Yu Lou
Birth: 10.07.1986 in Zhejiang, PR China

Education

Since 11/2012 **PhD study** in faculty of technical chemistry II, Technical University of Munich (TUM)
Topic: „Dry reforming of natural gas to produce synthesis gas“

04/2009 - 05/2012 **Master's Degree** at the Technical University of Munich (TUM)
Major subject: Organic Chemistry
Secondary subject: Analytic Chemistry
Degree: Master of Science (Grade 1.7)

Master-Thesis at the Technical University of Munich (Grade 1.3)
Topic: „Phenyl ether bond cleavage and hydrodeoxygenation of bio-derived phenolic dimer“

08/2008 - 02/2009 **German course in China**
Certificate: German language examination for university entrance
Level 2 (DSH-2)

09/2004 - 07/2008 **Bachelor study** in the college of chemistry, Zhejiang University, China
Degree: Bachelor of Science (Grade 85 in 100)

Bachelor-Thesis: „Regioselective routes to disubstituted dibenzo crown ether“

Practical Experiences

Since 11/2012 **Scientific research assistant** in faculty of technical chemistry II, Technical University of Munich (TUM)

Activities:

- Preparation, testing and characterization of catalysts for dry reforming of methane with special laboratory and analytical devices (TPD, TPR, BET, XRD, IR and UV-Vis spectroscopy, GC, GCMS)
- Internal and external presentation of research results
- Supervision of laboratory practical course, individual research internships and dissertations of chemistry and chemical engineering students

- Responsibility for TPD measurements and maintenance of test equipment
- Successful participation in the "Fundamental Aspects and Common Principles of Catalysis" course of the South German Catalysis Institute

01/2013 - 12/2015 **Participation in the EU project** with the aim of converting natural gas into synthesis gas.

Activities:

- Cooperation with research groups from Vienna and Budapest
- Characterization and testing of new materials synthesized within the framework of EU project
- Discussion and planning of new strategies

04/2010 - 12/2010 **Research assistant** in faculty of technical chemistry II, Technical University of Munich (TUM)
Topic: Methanol to olefins (MTO) reaction over acidic zeolite (ZSM-5) or zeotype materials
